

Theory of Interaction

YUXI FU

Shanghai Jiao Tong University

Theory of Interaction aims to provide a foundational framework for computation and interaction. It proposes four fundamental principles that characterize the common features of all models of computation and interaction. These principles suffice to support a model independent treatment of the two most important relationships in computer science, the equality between processes and the relative expressiveness between models. Based on the two relationships the theory of equality, the theory of expressiveness and the theory of completeness are developed.

1. FOUNDATION

Modern computing is all about interaction [Milner 1993a]. This is however not to say that the traditional notion of computing is not about interaction. The difference is due to the angle of observation. In Church-Turing's models of computation, the focus is on the closed systems, systems that never interact with any other systems, and the internal actions of the systems. So the models of computation are concerned with interactions within. On the other hand, the interest of the distributed computing and the mobile computing is in the open systems. In addition to its internal interactions, an open system interacts with another open system. The complexity of an open system is often caused by the interleavings of its internal interactions with its external actions and the nondeterministic timings of these interleavings.

Models of computation were proposed and studied in 1930's. Some well known models are the Recursive Function Model, the Turing Machine Model, the λ -calculus, and the Random Access Machine [Rogers 1987; Hopcroft and Ullman 1979; Barendregt 1984; van Emde Boas 1990]. By investigating the comparative power of these models, it was soon realized that all these models are equivalent in the sense that the partial functions definable in these models are all the same. The belief that all models of computation are equivalent in this sense has been referred to as Church-Turing Thesis. The original formulation of Church-Turing Thesis emphasizes on computability. It was revealed in subsequent studies, especially in the studies of algorithms [Dasgupta et al. 2006] and computational complexity [Papadimitriou 1994; Wegener 2005], that the equivalence of the models of computation actually holds at the operational level. There is a translation from one model of computation to another that preserves and reflects computations. The translation is not only effective, it is actually polynomial in complexity.

Milner [1980] pioneered the study to formalize the notion of interaction between open systems (processes) by his work on CCS. At about the same time, Hoare [1978] has also made significant contribution to the theory in his work on the well known programming language CSP. Since then the theory of process calculus in particular and the concurrency theory in general have proliferated. In fact the concurrency theory has developed so rapidly and the number of the proposed models has increased so dramatically that a call for a general theory of interaction has long been overdue. Looking back, one cannot help remarking that the fundamental notions like interaction, composition, localization, and interface (channel) were all present in CCS as well as CSP. A crucial tool, bisimulation, was introduced to concurrency by Park [1981] and Milner [1989a] in 1980's, which has greatly advanced the observation theory of processes ever since. An interesting account of the history of bisimulation in computer science can be found in [Sangiorgi 2009].

An issue that currently attracts more attention than ever is the relative expressiveness of process calculi. In view of the hundreds of process calculi [Nestmann 2006], if not more, that have been proposed, results on expressiveness are very far and few between. The issue is complicated by the lack of a consensus on the criteria for comparing the expressiveness. As Parrow has pointed in [Parrow 2006], if we have n process calculi and m sets of criteria, we end up with at least $n \times m \times n$ positive or negative results on expressiveness. Worse still there may well be con-

tradictory results since an expressiveness relationship from one calculus to another may be negative by one set of criteria and positive by another set of criteria. The truth is, as long as we are using two different sets of criteria, contradictory results would never be a surprise. This is definitely unacceptable for a theory that seeks to reveal the discipline of interaction. One source of the diversity is that too many process calculi have been manufactured with little industrial effort. The lack of constraints has led to a profusion of calculi that would fail any single set of criteria. If we are to look for a single set of sensible criteria applicable to some models, we will be at the same time ruling out a good few of others.

Another important issue is about what Abramsky [2006] has called expressive completeness. Should we impose a minimal expressive power on all models of interaction? A positive answer would be a very foundational assumption that provides a fundamental constraint. If a process calculus is intended to be an extension of a computation model, the expressive completeness should imply that within the calculus one should be able to code up all the computable functions. So in a unified theory for both computation models and interaction models, the expressive completeness should subsume the so-called Turing completeness discussed in literature. But how should we formalize the expressive completeness? Let's take a look at how Turing completeness is formalized in the theory of process calculus. Again different criteria have been proposed in literature [Maffeis and Phillips 2005]. The proof of Turing completeness according to these criteria typically amounts to constructing a map $\llbracket _ \rrbracket$ from the set of the computing objects of a computation model \mathbf{L} to a set of processes of a process calculus \mathbf{M} in such a way that a computation of say L is simulated by a tau action sequence of $\llbracket L \rrbracket$ and vice versa. Two such encodings are given in for example [Lanese et al. 2008] and [Busi et al. 2003; 2004]. The former tells the story of the expressiveness of the internal interactions of a higher order process calculus but totally ignores the external interacting power of the calculus. The encoding takes into account of the operational semantics of the computation model. However it falls far short of being a fully abstract interpretation. The latter translates a random access machine, an input value and an output value to the processes of CCS. A conspicuous deficiency of the latter encoding, due to the limitation of CCS, is the lack of something like 'value supply' or 'result delivery'. These two examples are representative in the sense that they regard the processes as closed systems when studying Turing completeness. The input values are not picked up from the environments properly, and the results are not targeted to any receivers.

One could give more examples demonstrating the lack of consensus, not to mention philosophies, in other parts of the theory of process calculus. But the point has been made. As much as it has benefited from the observational approach that tries to ignore all computations, the theory of process calculus has suffered from not paying enough attention to the fundamental role of the theory of computation. The theory of process calculus and the theory of computation have been two separate developments. A strategic move is to carry out the investigation in an integrated framework that does not favor one over the other. It is expected that both the theory of computation and the theory of process calculus should benefit from such an integration.

1.1 Theory of Interaction

The prime motivation for Theory of Interaction is to bridge the gap between the computation theory and the interaction theory. By adopting the view that interaction is computation seen from within and that computation is interaction seen from without, Theory of Interaction eliminates the distinctions between these two kinds of models from the outset. The benefit is that we may extend the results and methodologies well established for the computation models to models that account for both computation and interaction.

The ultimate goal of Theory of Interaction is to provide a framework in which one may formalize the foundational assumptions, for example the Church Turing Thesis, widely accepted in the major branches of computer science. Since postulates are formulated in terms of relations, one has to pin down the fundamental relationships in computer science before formalizing any postulates. These relationships must be about models and objects (processes, programs), there is nothing more basic than these two classes of entities. Hence the following two relationships.

- The first is the equality relationship on the processes. At an abstract level, one cannot think of a relationship on objects/processes/programs that is simpler than the equality relationship.
- The second is the expressiveness relationship formalizing the idea that one model is at least as expressive as another. All other relationships between the models are conceptually more complex.

Both the equality relationship and the expressiveness relationship must be defined in a model independent manner, otherwise there would be no way to formalize any postulates that apply to all models. Now the only way to achieve model independence is to introduce a number of principles that prescribe the common properties of all models. So we start with these principles.

1.2 Fundamental Principle

We will introduce four fundamental principles for Theory of Interaction. These principles introduce a set of minimal properties enough to define the two most important relationships.

1.2.1 Principle of Object. A *model of interaction* defines interactions. All interactions are performed by *processes*. An interaction is a *cooperation* between two processes. It is synchronous and atomic. A basic assumption in Theory of Interaction is that all interactions are conducted via *interfaces*.

Through interfaces are interactions possible; no interactions go without interfaces.

This assumption, borrowed from the theory of process calculus, is ground shaping. It forces us, from the very start, to answer some basic questions about the interfaces. Do we need to assume a different set of interfaces for every model of interaction? If our answer to the question is positive, we are implicitly assuming that an interface does have a mind of its own. If that was the case, why were interfaces not processes? It makes more sense to assume that interfaces are property free. This is why they are simply formalized as *names*. A name is the name of itself. It differs from another

name only in that they are distinct names. Since the names are propertyless, it does not matter which set of names a model is using. Without losing any generality we adopt the following convention:

There is only one infinite and countable set of interfaces. All models of interaction make use of this set of interfaces.

This simple assumption suggests that the interfaces are of a physical nature, whose existence is independent of any particular model.

So there are two kinds of syntactical objects in every model of interaction. In Theory of Interaction, we confine our attention to the models in which the names and the processes are the only proper objects. Other syntactical objects are either derivable or auxiliary.

Principle of Object. There are two kinds of objects; they are the names and the processes.

We will apply as much as possible the same syntactical notations to all models. We will write \mathcal{N} for the set of the names, ranged over by a, b, c, d, e, f, g, h . In the models we consider in this paper, an interaction happen between two processes. When two processes are connected at the two ends of an interface, an interaction can be fired. We often write a and \bar{a} to indicate the ‘positive’ and the ‘negative’ ends of the interface a .

When defining mobility, we need *name variables*. Let \mathcal{V}_n be the countable and infinite set of the name variables, ranged over by u, v, w, x, y, z . A name variable is a place holder. It can be bound by a prefix operation, in which case we say that the name variable is *bound*. A name variable is *free* if it is not bound.

The set $\mathcal{N} \cup \mathcal{V}_n$ will be ranged over by l, m, n, o, p, q . A *renaming* α is a partial map $\alpha : \mathcal{N} \rightarrow \mathcal{N}$ such that the domain of definition $dom(\alpha)$ is finite and that it is injective on $dom(\alpha)$. A renaming is often written explicitly as $\{b_1/a_1, \dots, b_n/a_n\}$. A *substitution* σ is a partial map $\sigma : \mathcal{V}_n \rightarrow \mathcal{N} \cup \mathcal{V}_n$ whose domain of definition $dom(\sigma)$ is finite. A substitution is often written as $\{p_1/x_1, \dots, p_n/x_n\}$. An *assignment* ρ is a partial function of type $\mathcal{V}_n \rightarrow \mathcal{N}$ whose domain of definition is cofinite.

For a model of interaction \mathbb{M} , there are syntactical objects called *terms*, or the \mathbb{M} -terms. The notation $\mathcal{T}_{\mathbb{M}}$ denotes the set of \mathbb{M} -terms, ranged over by R, S, T . When defining higher order calculi or some form of recursion, we need *term variables*. We write \mathcal{V}_t for the infinite countable set of the term variables, ranged over by X, Y, Z . A term variable can be bound by a prefix operation.

An *\mathbb{M} -process* is a proper \mathbb{M} -term. The \mathbb{M} -terms are introduced in order to define \mathbb{M} -processes. This is often necessary in a structural definition. A basic requirement for a term to be a process is that it does not contain any free variables of any kind. The notation $\mathcal{P}_{\mathbb{M}}$ stands for the set of the \mathbb{M} -processes, ranged over by L, M, N, O, P, Q .

A *term substitution* is a partial map $\varsigma : \mathcal{V}_t \rightarrow \mathcal{T}_{\mathbb{M}}$ whose domain of definition $dom(\varsigma)$ is finite. We often write $\{T_1/X_1, \dots, T_n/X_n\}$ for a term substitution. A *term assignment* ρ is a partial function of type $\mathcal{V}_t \rightarrow \mathcal{P}_{\mathbb{M}}$ whose domain of definition is cofinite.

We abbreviate a finite sequence of names c_1, \dots, c_n to \tilde{c} . Accordingly $(c_1) \dots (c_n)T$ is often abbreviated to $(\tilde{c})T$. Similarly we will write for example $\tilde{x}, \tilde{X}, \tilde{T}$ and \tilde{P} .

1.2.2 *Principle of Action.* An process either interacts with another process or performs an action on its own. The former is an *external* action whereas the latter is an *internal* action. An internal action is either a *single step computation*, or an *internal change-of-state*. An external action of a process is what a counterpart sees when the two processes are engaged in an interaction. For this reason, the external actions are the *observable* actions and the internal actions are the *unobservable* actions. The computations are special internal actions. When we are evaluating the performance of programs, as we do in complexity theory, our concern is often on computations. When we are actually doing programming, our focus has to cover interactions. From the point of view of the Theory of Interaction, the external actions and the internal actions carry the same weight.

Principle of Action. There are two aspects of the atomic actions, the internal aspect and the external aspect.

Syntactically we shall write $P \xrightarrow{\tau} P'$ to indicate that P evolves to P' after performing an internal action. The reflexive and transitive closure of $\xrightarrow{\tau}$ is denoted by \Longrightarrow , and the transitive closure of $\xrightarrow{\tau}$ by $\xrightarrow{\tau^+}$. For convenience we shall also write $P \rightarrow P'$ to mean that P evolves to P' after a single step computation, and $P \xrightarrow{\ell} P'$ that P evolves to P' after an internal change-of-state. The precise definitions of the single step computations and the change-of-state internal actions will be given after the equality on the processes is introduced. At this point we may understand that a single step computation does not change the interactability of a process, whereas a change-of-state internal action does change the interactability. The reflexive and transitive closure of \rightarrow is denoted by \rightarrow^* , and the transitive closure by \rightarrow^+ . We write $P \dashrightarrow$ if $P \rightarrow P'$ for no P' . A *computation* of a process P is either a finite sequence of single step computations

$$P \rightarrow P_1 \rightarrow \dots \rightarrow P_n$$

or an infinite sequence of single step computations

$$P \rightarrow P_1 \rightarrow \dots \rightarrow P_i \rightarrow \dots$$

We write $Cmp(P)$ for the set of the computations of P . A *complete computation* is either an infinite computation or a finite computation $P \rightarrow P_1 \rightarrow \dots \rightarrow P_n$ such that $P_n \dashrightarrow$.

Suppose \mathbb{M} is a model of interaction. Let the set $\mathcal{L}_{\mathbb{M}}$, ranged over by ℓ , be the set of the labels representing the external actions. We write

$$P \xrightarrow{\ell} P'$$

for the fact that P turns into P' after performing the action ℓ . The notation $\xrightarrow{\ell}$ is defined as follows:

$$\xrightarrow{\ell} \stackrel{\text{def}}{=} \rightarrow^* \xrightarrow{\ell}.$$

Let $\mathcal{L}_{\mathbb{M}}^*$ be the set of the finite strings of the elements of $\mathcal{L}_{\mathbb{M}}$. We write ℓ^* for an element of $\mathcal{L}_{\mathbb{M}}^*$. The empty string is denoted by ϵ . If $\ell^* = \ell_1 \dots \ell_n$, then the notation $P \xrightarrow{\ell^*} P'$ stands for $\exists P_1, \dots, P_{n-1}. P \xrightarrow{\ell_1} P_1 \dots \xrightarrow{\ell_{n-1}} P_{n-1} \xrightarrow{\ell_n} P'$. If $\ell^* = \epsilon$, then $P \xrightarrow{\ell^*} P'$ is the same as $P \rightarrow^* P'$. The set of the *actions* $\mathcal{A}_{\mathbb{M}}$ is the union

$\mathcal{L}_{\mathbb{M}} \cup \{\tau\}$, ranged over by λ . We say that P' is a *descendant* of P if $P \xrightarrow{\lambda_1} \dots \xrightarrow{\lambda_n} P'$ for some $n \geq 0$. According to the definition P is a descendant of itself. The set of the descendants of P is denoted by $Dscd(P)$.

1.2.3 Principle of Observation. The only way to make an observation on a process is to interact with it. There is no other way. If an interaction pattern between O and P is not similar to any interaction pattern between O and Q , then in the eyes of O the processes P and Q are different. In other words, O can observe a difference between P and Q . While making an observation, an observer is simultaneously being observed by the observee. It follows that the observers and the observees must be in reciprocal positions. This reciprocity has serious implications, one of which is stated as follows:

The observers have the same observing power as the observees, no more, no less.

In a *closed* model of processes, having a stronger observing power is unnecessary, and having a weaker observing power is insufficient.

What makes it possible for two processes to observe each other? The observation is possible if they are composed at the same level to form a bigger system. A *composition* differs from a parallel deployment precisely in that in the former the components may interact whereas in the latter no such interactions may happen. Composition and interaction come hand in hand. In terms of observation, this can be stated as follows:

Observation is the reason for composition; composition enables observation.

The standard notation for the *composition operator* is $'|'$. In $P|Q$ the operator $'|'$ connects the processes P, Q , allowing them to interact at common interfaces. Systems composed of many components admit a great deal of interactions. However interactions without any control are hardly of any use. One effective approach to increase the control on interaction is to use *localization operator*. For a process P , we write $(a)P$ for the process obtained from P by restricting the use of the name a . Here the name a is localized, meaning that in $(a)P$ the interface a must be used within P and that P cannot interact with another process through the interface a . In other words, P cannot be observed at a . Investigations in the theory of process calculus have shown that the localization operator is of fundamental importance. Without it most calculi would be too weak to be interesting. The motto is stated as follows:

Non-observation is the reason for localization; localization disables observation.

A mainstream practice in the theory of process calculus is that the notion of observation is assumed invariant in all process calculi. If one thinks of it, this assumption is really the very basis for the expressiveness study.

The way of making observations is the same in all models of interaction. In other words, the notion of observation is model independent.

Technically this assumption on observation forces one to adopt the following fundamental principle.

Principle of Observation. There are two universal operators, the composition operator and the localization operator.

Principle of Observation implies that the semantics of the two operators are essentially the same in all models of interaction. Using the labeled transition systems [Plotkin 1981; Aceto et al. 2001], the operational semantics of the composition operator can be defined in the standard way. There are two structural rules:

$$\frac{S \xrightarrow{\lambda} S'}{S|T \xrightarrow{\lambda} S'|T} \quad \frac{T \xrightarrow{\lambda} T'}{S|T \xrightarrow{\lambda} S|T'} \quad (1)$$

There are semantic rules that define the cooperations between the two components of a composition. Although they cannot be completely specified at this level of abstraction, they always take the following general form.

$$\frac{S \xrightarrow{\ell} S' \quad T \xrightarrow{\bar{\ell}} T'}{S|T \xrightarrow{\tau} R'} \quad (2)$$

The symmetric version of (2) is always omitted. In (2) the external actions ℓ and $\bar{\ell}$ are the contributions of S and T respectively in the cooperation, and R' is defined from $S', T', \ell, \bar{\ell}$. For the localization operator, the structural rule is defined by the following rule.

$$\frac{T \xrightarrow{\lambda} T'}{(a)T \xrightarrow{\lambda} (a)T'} \quad a \text{ does not appear in } \lambda. \quad (3)$$

The semantic rules for the localization operator are of the following pattern.

$$\frac{T \xrightarrow{\ell} T'}{(a)T \xrightarrow{(a)\ell} T'} \quad a \text{ does not appear in } \ell \text{ as an interface name.} \quad (4)$$

The precise interpretation of the side condition of (4) is model dependent.

Since the composition operator is symmetric and associative, we shall use the product notation

$$\prod_{i \in \{1, \dots, n\}} T_i$$

for the composite term $((\dots (T_1 | T_2) | \dots) | T_{n-1}) | T_n$. The composition of i copies of T is denoted by

$$\prod_i T.$$

We shall say that the name a in $(a)T$ is a *local name*. A name is a *global name* if it is not local. The localization operation introduces a hierarchical structure in a term. In $(a)(S|(a)T)$ for example, S and T cannot interact at a . We write $gn(-)$ and $ln(-)$ for the functions that return the set of the global names, and respectively the set of the local names. We also write $n(-)$ for the function that returns the set of all the names.

We shall apply the α -conversion to both the local names and the bound name variables. Based on α -conversion, we shall make it a convention that no conflict and confusion about names and name variables can ever arise.

We can now describe the observations using the universal operators. For example the following internal action sequence is an observation on P .

$$(b)(O_2 | (a)(O_1 | P)) \xrightarrow{\tau} (b)(O_2 | (a)(O'_1 | P')) \xrightarrow{\tau} \xrightarrow{\tau} (b)(O'_2 | (a)(O'_1 | P')) \dots$$

The following universal definition of environment is rendered possible by the Principle of Observation.

Definition 1.1. An *environment* $C[_]$ of \mathbb{M} is either $[_]$, or $(c)C'[_]$, or $P | C'[_]$, or $C'[_] | P$, where $c \in \mathcal{N}$, $P \in \mathcal{P}_{\mathbb{M}}$ and $C'[_]$ is an environment of \mathbb{M} .

1.2.4 Principle of Consistency. Theory of Interaction is *consistent* in the sense that not all processes of a model can be identified. Since the theory is meant to provide a unification framework, the equality or inequality of two processes should be judged from the point of view of both computation and interaction. In terms of the ability to perform internal actions, what could be the biggest difference between two processes? The difference cannot be sharper than that

- one always terminates, and
- the other may engage in an infinite sequence of internal actions.

We say that a process P is *terminating* if it does not have any infinite sequence of internal actions $P \xrightarrow{\tau} \xrightarrow{\tau} \dots$; it is *divergent* otherwise. In the light of the external actions, what could be the biggest difference between two processes? The difference cannot be sharper than that

- one can interact, and
- the other cannot interact with any process.

We say that a process P is *observable*, notation $P \Downarrow$, if $\exists T. \exists \ell. P \Longrightarrow \xrightarrow{\ell} T$; otherwise it is *unobservable*, notation $P \not\Downarrow$.

At the present level of abstraction, the consistency of a model can only mean that the most different processes should never be equated.

Principle of Consistency. A terminating process is never equal to a divergent process. An observable process is never equal to an unobservable process.

In Theory of Interaction all models are assumed to have the process $\mathbf{0}$ that cannot do any internal or external actions. Principle of Consistency not only points out what processes can be distinguished, but also implies what cannot be distinguished. The following statement can be seen as a corollary of the principle.

All terminating unobservable processes are equal to $\mathbf{0}$.

So we might as well think of a terminating unobservable process as a terminated process.

1.3 Computability Model

From the point of view of Theory of Interaction, a computation model is a simplification of an interaction model obtained by disabling all global interfaces. Different computation models can be extended to different interaction models. Among all these extensions a minimal model that embodies the fundamental idea of computability and interactability would be very useful. From our perspective an interactional extension of the computable functions may serve as such a model.

The first step to recover the interaction model from the computable functions is to recall that what makes us to introduce the channels in the first place is precisely to internalize actions like input-a-value and output-a-result. For the unary computable function $f(x)$ the intuition is that its operational semantics should describe the following three stage activities:

- (1) it picks up a natural number from the environment;
- (2) it then carries out the computation prescribed by the function; and finally
- (3) it delivers the result of the computation to targeted receivers.

Depending on the type of the ambient environment, the inputs and the outputs are done with the help of particular channels. The Computability Model, the \mathbb{C} -calculus, is the minimal extension of the computable function model that supports (1) through (3). In \mathbb{C} the atomic processes are either functions or values with the capacity to interact. The processes are generated by the following simple grammar:

$$P := \mathbf{0} \mid \Omega \mid F_a^b(f(x)) \mid \bar{a}(\underline{i}) \mid P \mid P,$$

where $f(x)$ is a unary computable function, and \underline{i} is a natural number, underlined to avoid confusion. The process $F_a^b(f(x))$, in which the names a, b must be distinct, can input a natural number, say \underline{m} , at channel a . It becomes $\bar{b}(\underline{n})$ if $f(\underline{m}) = \underline{n}$ and Ω if $f(\underline{m})$ is undefined. The semantics of $F_a^b(f(x))$ is given by the following rules.

$$\frac{}{F_a^b(f(x)) \xrightarrow{a(\underline{m})} \bar{b}(\underline{n})} \text{ if } f(\underline{m}) = \underline{n}. \quad \frac{}{F_a^b(f(x)) \xrightarrow{a(\underline{m})} \Omega} \text{ if } f(\underline{m}) \text{ is undefined.}$$

The sole action of $\bar{a}(\underline{i})$ is to release the natural number \underline{n} at the channel a . The process Ω is special in that it can only diverge. These operational behaviors are defined by the following rules.

$$\frac{}{\bar{a}(\underline{n}) \xrightarrow{\bar{a}(\underline{n})} \mathbf{0}} \quad \frac{}{\Omega \xrightarrow{\tau} \Omega}$$

The transition rules for interaction are standard:

$$\frac{P \xrightarrow{a(\underline{n})} P' \quad Q \xrightarrow{\bar{a}(\underline{n})} Q'}{P \mid Q \xrightarrow{\tau} P' \mid Q'} \quad \frac{P \xrightarrow{\bar{a}(\underline{n})} P' \quad Q \xrightarrow{a(\underline{n})} Q'}{P \mid Q \xrightarrow{\tau} P' \mid Q'}$$

The structural rules are also standard:

$$\frac{P \xrightarrow{\lambda} P'}{P \mid Q \xrightarrow{\lambda} P' \mid Q} \quad \frac{Q \xrightarrow{\lambda} Q'}{P \mid Q \xrightarrow{\lambda} P \mid Q'}$$

The definition of the Computability Model is now complete. Its fundamental role in Theory of Interaction will be revealed later.

2. MODEL OF INTERACTION

Let's begin with an outline of how the models of interaction are defined. Suppose \mathbb{M} is a model. The set $\mathcal{T}_{\mathbb{M}}$ of the \mathbb{M} -terms is defined by an abstract grammar in the style of BNF. It looks typically like the following:

$$T := \mathbf{0} \mid T \mid T' \mid (c)T \mid T_3 \mid \dots \mid T_n.$$

Each of $\{T_3, \dots, T_n\}$ introduces an operator. In the spirit of Theory of Interaction, we write $\mathbf{0}$, $T \mid T'$ and $(c)T$ as default and omit them from the definition of an abstract grammar. The semantics of \mathbb{M} is defined by a labeled transition system, which is a tuple $(\mathcal{T}_{\mathbb{M}}, \mathcal{A}_{\mathbb{M}}, \longrightarrow_{\mathbb{M}})$ where the transition relation $\longrightarrow_{\mathbb{M}}$ is a subset of $\mathcal{T}_{\mathbb{M}} \times \mathcal{A}_{\mathbb{M}} \times \mathcal{T}_{\mathbb{M}}$. We write $S \xrightarrow{\lambda}_{\mathbb{M}} T$ for $(S, \lambda, T) \in \longrightarrow_{\mathbb{M}}$. The relation $\longrightarrow_{\mathbb{M}}$, where the subscript is almost always omitted, is generated by mutual inductions on $\mathcal{T}_{\mathbb{M}}$. The inductions are given by axioms and rules and are composed of two parts:

- the axioms and rules specific to \mathbb{M} ;
- the rules introduced in Section 1.2.3.

When defining the semantics of a model, the structural rules (1) and (3) will always be omitted. Quite often a semantic rule like (4) is also omitted as long as the interface names of the external actions have been specified. However the interaction rules like (2) will always be given.

In this section, we review three well-known models of interaction. They will be the running examples throughout the paper. Their legitimacy will be justified later. Our formulations of these models are not quite the same as the standard ones. Extensive studies of these models in a manner advocated by Theory of Interaction can be found in the satellite papers [Cai and Fu 2010; Fu 2011b; Fu and Zhu 2011].

2.1 Machine Model

We now take a look at a machine model for interaction. Such a model is promoted from the machine models for computation. An *Atomic Interactive Machine* is basically obtained from a Turing Machine [Hopcroft and Ullman 1979] by replacing the input tape, the work tape and the output tape by input channels, accumulator and output channels respectively. It can also be seen as an extension of a Counter Machine [van Emde Boas 1990] with input and output channels. Formally an Atomic Interactive Machine \mathbb{M} is defined by Cai and Fu [2010] as a tuple $(I, O, R_0(\underline{n}_0), R_1(\underline{n}_1), A(\underline{n}), P, \underline{l})$ where the components (see Fig. 1) have the following interpretations:

- I is the finite set of *input channels* through each of which the machine may input one natural number at a time.
- O is the finite set of *output channels* through each of which the machine may output one natural number at a time.
- R_0, R_1 are two *registers*, either of which may store a natural number. The natural numbers $\underline{n}_0, \underline{n}_1$ are the current values of the registers.
- A is the *accumulator* which may store a natural number. The natural number \underline{n} is the current value of the accumulator.

Fig. 1. Atomic Interactive Machine.

— P is the *program* that consists of a finite list of *instructions*. The program appears in the following shape:

$$\begin{aligned} \underline{1} &: I_1 \\ \underline{2} &: I_2 \\ &\vdots \\ \underline{n} &: I_n \\ \underline{n+1} &: Stop \end{aligned}$$

where $n \geq 0$. Here $\underline{1}, \dots, \underline{n+1}$ are the *addresses* of the instructions. The last instruction of the program must be *Stop*. For each $\underline{i} \in \{\underline{1}, \dots, \underline{n+1}\}$, we write $P(\underline{i})$ for the i -th instruction of the program P .

— \underline{l} is the address of the *current* instruction. It takes value in $\{\underline{1}, \dots, \underline{n+1}\}$.

The instructions are classified into two groups, those that move data around between the machines, and those that manipulate the data within a machine. The instructions in the first group are of two types:

- (i) *Input* a , where $a \in \mathbb{I}$, picks up a natural number at channel a and update the content of A by the received number.
- (o) *Output* b , where $b \in \mathbb{O}$, fetches the number stored in A and delivers the number at channel b .

The instructions in the second group are of three types. Only one instruction is of the first type.

- (s) *Stop* is the instruction that terminates the machine execution.

Two instructions are of the second type.

- (r) *Read* i , where i is either 0 or 1, copies the content of R_i to A .
- (w) *Write* i , where i is either 0 or 1, copies the content of A to R_i .

The instructions of the third type define arithmetic operations. There are many choices for these instructions. The reader might have his/her favorite combination. In this paper we shall not be specific about these instructions.

The semantics of the Atomic Interactive Machines is given by a labeled transition system. The rules about the input and output instructions are as follows.

$$\frac{P(l) = \text{Input } a}{(l, O, R_0(\underline{n}_0), R_1(\underline{n}_1), A(\underline{n}), P, \underline{l}) \xrightarrow{a(\underline{m})} (l, O, R_0(\underline{n}_0), R_1(\underline{n}_1), A(\underline{m}), P, \underline{l} + 1)}$$

$$\frac{P(l) = \text{Output } b}{(l, O, R_0(\underline{n}_0), R_1(\underline{n}_1), A(\underline{n}), P, \underline{l}) \xrightarrow{\bar{b}(\underline{n})} (l, O, R_0(\underline{n}_0), R_1(\underline{n}_1), A(\underline{n}), P, \underline{l} + 1)}$$

The rules about the read and write instructions are as follows:

$$\frac{P(l) = \text{Read } i \text{ and } i \in \{0, 1\}}{(l, O, R_0(\underline{n}_0), R_1(\underline{n}_1), A(\underline{n}), P, \underline{l}) \xrightarrow{\tau} (l, O, R_0(\underline{n}_0), R_1(\underline{n}_1), A(\underline{n}_i), P, \underline{l} + 1)}$$

$$\frac{P(l) = \text{Write } 0}{(l, O, R_0(\underline{n}_0), R_1(\underline{n}_1), A(\underline{n}), P, \underline{l}) \xrightarrow{\tau} (l, O, R_0(\underline{n}), R_1(\underline{n}_1), A(\underline{n}), P, \underline{l} + 1)}$$

$$\frac{P(l) = \text{Write } 1}{(l, O, R_0(\underline{n}_0), R_1(\underline{n}_1), A(\underline{n}), P, \underline{l}) \xrightarrow{\tau} (l, O, R_0(\underline{n}_0), R_1(\underline{n}), A(\underline{n}), P, \underline{l} + 1)}$$

The Atomic Interactive Machines are so defined to facilitate the exchanges of information among individual machines. The general *Interactive Machines* are syntactically defined by the following grammar:

$$M := \text{AIM} \mid (c)M \mid M \mid M'$$

where AIM's are the Atomic Interactive Machines. Let \mathbb{IM} denote the Interactive Machine Model. The semantics of \mathbb{IM} follows the general methodology. The interaction rule for example is defined by the following rule and its symmetric version.

$$\frac{M \xrightarrow{a(\underline{n})} M' \quad N \xrightarrow{\bar{a}(\underline{n})} N'}{M \mid N \xrightarrow{\tau} M' \mid N'}$$

The machine model \mathbb{IM} can be extended to \mathbb{INM} , the Interactive Nondeterministic Machine Model. Both \mathbb{IM} and \mathbb{INM} are investigated in [Cai and Fu 2010].

2.2 Function Model

The value-passing calculus \mathbb{VPC} is the recursion theory [Rogers 1987] reincarnated in an interactive framework. Let's pause for a minute and think about what need be introduced to define all the recursive functions. The followings ought to be clear.

- To admit the input actions input terms of the form $a(x).T$ are introduced.
- To support the output actions output terms of the form $\bar{a}(\cdot).T$ are incorporated.
- To define minimization, conditional terms of the form *if* φ *then* T are necessary.
- To interpret recursion, replication is a minimal option.

The model \mathbb{VPC} is defined on top of the first order Peano Theory [Fu 2011b]. We write $\text{PA} \vdash \varphi$ if φ can be derived in the Peano Theory. Formally the set $\mathcal{T}_{\mathbb{VPC}}$

of the \mathbb{VPC} -terms is generated by the following grammar.

$$T := \sum_{1 \leq i \leq k} a(x).T_i \mid \sum_{1 \leq i \leq k} \bar{a}(t_i).T_i \mid \text{if } \varphi \text{ then } T \mid !a(x).T \mid !\bar{a}(t).T.$$

In the input choice $\sum_{1 \leq i \leq k} a(x).T_i$ and the output choice $\sum_{1 \leq i \leq k} \bar{a}(t_i).T_i$, the guard $a(x)$ is an input prefix and the guard $\bar{a}(t_i)$ is an output prefix. The input prefix $a(x)$ binds the term variable x in the term it applies. A variable is free if it is not bound. The set $\mathcal{P}_{\mathbb{VPC}}$ of the \mathbb{VPC} -processes consists of those \mathbb{VPC} -terms that do not contain any free variables. The term *if φ then T* is a conditional term in which φ is a boolean expression. Often we write $[\varphi]T$ as a syntactical abbreviation for *if φ then T* . A finite set of boolean expressions $\{\varphi_i\}_{i \in I}$ is mutually exclusive if $\text{PA} \vdash (\varphi_i \wedge \varphi_j \Rightarrow \perp)$ for all $i, j \in I$ such that $i \neq j$. Given such a family, one could define the conditional choice $\sum_{i \in I} [\varphi_i]T_i$ as follows:

$$\sum_{i \in I} [\varphi_i]T_i \stackrel{\text{def}}{=} \prod_{i \in I} [\varphi_i]T_i.$$

A special case of the conditional choice is the following *if_then_else_* term:

$$\text{if } \varphi \text{ then } S \text{ else } T \stackrel{\text{def}}{=} [\varphi]S \mid [\neg\varphi]T.$$

It is obvious that at most one of S, T can be fired. For the same reason, at most one summand of $\sum_{i \in I} [\varphi_i]T_i$ may proceed further.

Using the label set $\mathcal{L}_{\mathbb{VPC}} = \{a(\underline{n}), \bar{a}(\underline{n}) \mid a \in \mathcal{N} \wedge \underline{n} \text{ is a natural number}\}$, the semantics of \mathbb{VPC} can be defined by the following labeled transition system, where j ranges over $\{1, \dots, k\}$ in the action rules.

Action

$$\frac{}{\sum_{1 \leq i \leq k} a(x).T_i \xrightarrow{a(\underline{n})} T_j\{\underline{n}/x\}} \quad \frac{}{\sum_{1 \leq i \leq k} \bar{a}(t_i).T_i \xrightarrow{\bar{a}(\underline{n})} T_j} \quad \text{PA} \vdash t_j = \underline{n}.$$

Interaction

$$\frac{S \xrightarrow{a(\underline{n})} S' \quad T \xrightarrow{\bar{a}(\underline{n})} T'}{S \mid T \xrightarrow{\tau} S' \mid T'}$$

Condition

$$\frac{T \xrightarrow{\lambda} T'}{\text{if } \varphi \text{ then } T \xrightarrow{\lambda} T'} \quad \text{PA} \vdash \varphi.$$

Recursion

$$\frac{}{!a(x).T \xrightarrow{a(\underline{n})} T\{\underline{n}/x\} \mid !a(x).T} \quad \frac{}{!\bar{a}(t).T \xrightarrow{\bar{a}(\underline{n})} T \mid !\bar{a}(t).T} \quad \text{PA} \vdash t = \underline{n}.$$

In many occasions the variant of \mathbb{VPC} with the input and the output prefixes in place of the guarded choices is sufficient. We write \mathbb{VPC}^- for this variant. Our treatment of \mathbb{VPC} is more formal than the ones found in literature. A detailed exposure of our approach can be found in [Fu 2011b].

2.3 Program Model

Church's λ -calculus [Barendregt 1984] has played a key role both in mathematical logic and in understanding the operational issues concerning (functional) programming. The lazy λ -calculus [Abramsky 1988] is the variant whose operational semantics is purely computational. It appears at first sight that the interactive model of the lazy λ -calculus is straightforward. Its syntax could be defined by the following grammar:

$$T := X \mid a(X).T \mid \bar{a}\langle T \rangle.T.$$

Unfortunately the model so defined is not a legal citizen in Theory of Interaction. See Section 5.2.2 for explanation. A crucial paradigm shift from the functional scenario to the object oriented scenario was made by Milner et al. [1992]. Instead of passing around processes, the π -processes send and receive names. The set \mathcal{T}_π of the π -terms is generated by the following grammar:

$$T := \sum_{1 \leq i \leq k} n(x).T_i \mid \sum_{1 \leq i \leq k} \bar{n}m_i.T_i \mid [p=q]T \mid [p \neq q]T \mid !n(x).T \mid !\bar{n}m.T.$$

The match operator $[- = -]$ and the mismatch operator $[- \neq -]$ are extremely important in both theory and practice. They are independent and conservative over the π -calculus without the conditionals [Fu and Lu 2010]. The name variable x in $n(x).T$ is bound. The set \mathcal{P}_π of the π -processes consists of those π -terms that contain no free name variables. The label set \mathcal{L}_π is $\{ac, \bar{a}c, \bar{a}(c) \mid a, c \in \mathcal{N}\}$. The semantics of π is defined by the following rules, where j ranges over $\{1, \dots, k\}$.

Action

$$\frac{}{\sum_{1 \leq i \leq k} a(x).T_i \xrightarrow{ac} T_j\{c/x\}} \quad \frac{}{\sum_{1 \leq i \leq k} \bar{a}m_i.T_i \xrightarrow{\bar{a}c} T_j} \quad m_j \text{ is } c$$

Interaction

$$\frac{S \xrightarrow{ac} S' \quad T \xrightarrow{\bar{a}c} T'}{S \mid T \xrightarrow{\tau} S' \mid T'} \quad \frac{S \xrightarrow{ac} S' \quad T \xrightarrow{\bar{a}(c)} T'}{S \mid T \xrightarrow{\tau} (c)(S' \mid T')}$$

Condition

$$\frac{T \xrightarrow{\lambda} T'}{[c=c]T \xrightarrow{\lambda} T'} \quad \frac{T \xrightarrow{\lambda} T'}{[a \neq b]T \xrightarrow{\lambda} T'}$$

Recursion

$$\frac{}{!a(x).T \xrightarrow{ac} T\{c/x\} \mid !a(x).T} \quad \frac{}{!\bar{a}c.T \xrightarrow{\bar{a}c} T \mid !\bar{a}c.T}$$

Some variants of the π -calculus can be obtained by imposing additional syntactical restrictions. Let π^- be obtained from the π -calculus by replacing the guarded choice operators by the plain prefix operator. If the match/mismatch operator is further removed from π^- , we get π^M , the minimal π -calculus. For a comprehensive theory of the π -calculus and its variants, the reader is referred to the satellite paper by Fu and Zhu [2011].

3. THEORY OF EQUALITY

Theory of equality studies observational equalities of processes. In line with the spirit of Theory of Interaction, we shall be focusing exclusively on model independent equalities. Conceivably there are a number of choices. What we are looking for is *the* equality on the processes. Our strategy to uncover the definition of this equality is to derive several corollaries from the four foundational principles. The properties stated in these corollaries are minimal in the sense that none of them can be properly weakened. We then turn these minimal properties into defining properties. What we get is the absolute equality. Here the word ‘absolute’ refers to minimality, model independence, and uniqueness. The success of Theory of Interaction depends on the fact that if we strengthen or weaken the definition of the absolute equality, we would get an equivalence subject to criticism.

Before proceeding ahead, a review of some standard terminologies is in order. A (binary) relation \mathcal{R} on \mathbb{M} is a subset of $\mathcal{P}_{\mathbb{M}} \times \mathcal{P}_{\mathbb{M}}$. It is reflexive if $\forall P \in \mathcal{P}_{\mathbb{M}}. (P, P) \in \mathcal{R}$, symmetric if $(P, Q) \in \mathcal{R}$ implies $(Q, P) \in \mathcal{R}$, and transitive if $(N, P) \in \mathcal{R}$ and $(P, Q) \in \mathcal{R}$ imply $(N, Q) \in \mathcal{R}$. We will often use the infix notation PRQ for $(P, Q) \in \mathcal{R}$. Let \mathcal{R}^i be the composition of i copies of \mathcal{R} with \mathcal{R}^0 being the identity relation. The reflexive and transitive closure $\bigcup_{i \in \omega} \mathcal{R}^i$ of \mathcal{R} is denoted by \mathcal{R}^* .

Definition 3.1. A relation \mathcal{R} on \mathbb{M} is *closed* if the following statements are valid:

- (1) For each $a \in \mathcal{N}$, $(a)P \mathcal{R} (a)Q$ whenever PRQ .
- (2) For each $O \in \mathcal{P}_{\mathbb{M}}$, $O|P \mathcal{R} O|Q$ and $P|O \mathcal{R} Q|O$ whenever PRQ .

A relation \mathcal{S} from \mathbb{M} to \mathbb{M}' is a subset of $\mathcal{P}_{\mathbb{M}} \times \mathcal{P}_{\mathbb{M}'}$. It is total if $\forall P \in \mathcal{P}_{\mathbb{M}}. \exists Q \in \mathcal{P}_{\mathbb{M}'}.(P, Q) \in \mathcal{S}$. Given a relation \mathcal{S} , the reverse relation is denoted by \mathcal{S}^{-1} . The composition of two relations $\mathcal{S}_0, \mathcal{S}_1$ is denoted by $\mathcal{S}_0; \mathcal{S}_1$, or even by $\mathcal{S}_0\mathcal{S}_1$, where the range set of \mathcal{S}_0 must be the same as the domain set of \mathcal{S}_1 .

3.1 Equality for Evolving Object

Computations are carried out over time. Interactions are conducted in space. The equalities for the processes, the self evolving and interacting objects, must span in both *time* and *space*. They should never be refuted by any computation or interaction.

Time, space, computation, and interaction are all we have in mind when looking for *the* equality on the processes.

3.1.1 Time Invariance. The equality = on the processes must take into account of the dynamic self evolutions of the processes. What if

$$P = Q \implies Q'$$

for possibly an infinite number of distinct Q' ? If for some Q'' there does not exist any P' such that

$$P \implies P' = Q''$$

then the process Q might silently evolve into some state to which P has no matching state. If such situations may occur, how can = even be considered an equality in the first place? The point is that, when left alone, processes evolve by themselves

over time. The self evolutions can be neither controlled nor detected. If the equality $P = Q$ holds right now, it should be possible that the equality is maintained at any point in future. Moreover the maintenance is done in a way that the history of the equality can be traced when going backwards in time. In Theory of Interaction the slogan is this:

Equal objects have been equal in history and will be equal in future.

It is not trivial to formalize this proposition for self evolving objects. In our opinion the next definition, introduced by van Glabbeek and Weijland [1989], captures precisely the future aspect of the above slogan.

Definition 3.2. A binary relation \mathcal{R} is a *bisimulation* if it validates the following bisimulation property:

1. If $Q\mathcal{R}^{-1}P \xrightarrow{\tau} P'$ then one of the following statements is valid:
 - (i) $Q \Longrightarrow Q'$ for some Q' such that $Q'\mathcal{R}^{-1}P$ and $Q'\mathcal{R}^{-1}P'$.
 - (ii) $Q \Longrightarrow Q''\mathcal{R}^{-1}P$ for some Q'' such that $\exists Q'.Q'' \xrightarrow{\tau} Q'\mathcal{R}^{-1}P'$.
2. If $PRQ \xrightarrow{\tau} Q'$ then one of the following statements is valid:
 - (i) $P \Longrightarrow P'$ for some P' such that $P'\mathcal{R}Q$ and $P'\mathcal{R}Q'$.
 - (ii) $P \Longrightarrow P''\mathcal{R}Q$ for some P'' such that $\exists P'.P'' \xrightarrow{\tau} P'\mathcal{R}Q'$.

It is important that the bisimulation property is stated in terms of internal actions. External actions are model dependent and consequently cannot be explicitly referred to in any model independent definition.

The property alluded in Definition 3.2 is that if $P = Q$ and P changes the state to P' in a single step, then Q may evolve to Q'' via a finite sequence of internal actions that do not change the state; and then changes the state from Q'' to Q' in a single step to match $P \xrightarrow{\tau} P'$.

3.1.2 Space Invariance. According to the Principle of Observation, if M is equal to N and P is equal to Q , then the result of M observing P should be no different from the result of N observing Q . But what does it mean that two observations are not different? The only possible interpretation is that the result of L observing $M|P$ should be no different from the result of O observing $N|Q$ whenever L is equal to O . In other words, $M|P$ and $N|Q$ must be equal. Now if no process may ever observe any difference between P and Q , then no process that does not make use of the name a can ever observe any difference between P and Q . This is equivalent to saying that $(a)P$ and $(a)Q$ are equal. To conclude, the equality for the processes must be closed under both composition and localization. It is in this sense that the equality for the processes spans in space.

Definition 3.3. A binary relation \mathcal{R} is *extensional* if the following extensionality property holds:

- (i) If $M\mathcal{R}N$ and $P\mathcal{R}Q$ then $(M|P)\mathcal{R}(N|Q)$;
- (ii) If $P\mathcal{R}Q$ then $(a)P\mathcal{R}(a)Q$ for every $a \in \mathcal{N}$.

The Principle of Observation guarantees that extensionality is a model independent property. It will become clear that condition (ii) of Definition 3.3 is indispensable. Without it we would not be able to distinguish between $!\tau|!a|b$ and

$! \tau | ! a | c$ in a model independent way, bearing in mind that the external actions are model dependent. The relationship between the extensional relations and the closed relations is pointed out in the following lemma.

LEMMA 3.4. *The following statements are valid:*

- (1) *If \mathcal{R} is reflexive and extensional, then \mathcal{R} is closed.*
- (2) *If \mathcal{R} is closed, then \mathcal{R}^* is extensional.*

When reasoning about process equality, it is often necessary to construct the extensional closure operation on a relation. It is therefore convenient to make available the following definition.

Definition 3.5. The *extensional closure* \mathcal{R}° of a binary relation \mathcal{R} is inductively defined as follows:

$$\begin{aligned} \mathcal{R}_0 &\stackrel{\text{def}}{=} \mathcal{R} \\ &\vdots \\ \mathcal{R}_{i+1} &\stackrel{\text{def}}{=} \mathcal{R}_i \cup \left\{ \begin{array}{l} ((a)P, (a)Q) \\ (L | M, N | O) \end{array} \mid \begin{array}{l} a \in \mathcal{N} \text{ and } P\mathcal{R}_i Q \\ L\mathcal{R}_i N \text{ and } M\mathcal{R}_i O \end{array} \right\} \\ &\vdots \\ \mathcal{R}^\circ &\stackrel{\text{def}}{=} \bigcup_{i \in \omega} \mathcal{R}_i \end{aligned}$$

Clearly a binary relation \mathcal{R} is extensional if and only if $\mathcal{R} = \mathcal{R}^\circ$.

3.1.3 *Computation Invariance.* The equality $=$ on the processes must also answer to the question on divergence. What if

$$P = Q \xrightarrow{\tau} Q_1 \xrightarrow{\tau} Q_2 \dots Q_i \xrightarrow{\tau} Q_{i+1} \dots$$

where Q can engage in an infinite internal action sequence? If P always eventually interacts with some environment, then intuitively it is not completely equivalent to Q since an infinite internal action sequence can preempt any interactions with any environments. A standard solution to the divergence problem is to impose the divergence preservation condition which requires that P is divergent if and only if Q is divergent. But the condition does not seem to fit well with the idea of bisimulation. Let's see an example. Suppose A is the CCS process $(c)((\tau.c.\text{good} + \tau) | \bar{c}.\text{good} + \tau)$. More often than not, the process $A | \mu X.\tau.X$ is thought to be equivalent to A . Both are divergent. There is however good reasons why they should not be equated. A divergent computation of $A | \mu X.\tau.X$ may never produce anything good. On the other hand, A keeps on producing something good after every two consecutive internal actions. An improvement on the divergence preservation condition requires that an infinite internal action sequence of Q is *bisimulated* by an infinite internal action sequence of P , and vice versa. This leads to the next definition that captures part of the Principle of Consistency.

Definition 3.6. A binary relation \mathcal{R} is *codivergent* if the following codivergence property holds whenever PRQ :

- If $P \xrightarrow{\tau} P_1 \xrightarrow{\tau} \dots \xrightarrow{\tau} P_{i+1} \dots$ is an infinite internal action sequence then $\exists Q'. \exists i \geq 1. Q \xRightarrow{\tau} Q' \mathcal{R}^{-1} P_i$;
- If $Q \xrightarrow{\tau} Q_1 \xrightarrow{\tau} \dots \xrightarrow{\tau} Q_{i+1} \dots$ is an infinite internal action sequence then $\exists P'. \exists i \geq 1. P \xRightarrow{\tau} P' \mathcal{R} Q_i$.

It is obvious that a codivergent relation is divergence preserving.

3.1.4 Interaction Invariance. The equality $=$ on the processes must also take into account of the dynamic interactions between the processes and the environments. If $P = Q$ then P and Q should exert similar influence on, or inflict comparable damage to an environment. Since we are interested in the minimal properties the equality has to satisfy, we may choose to settle on the following property: If $P = Q$ and one of P, Q can interact with an environment then the other can interact with an environment as well. We say that P and Q are *equipollent* if $P \Downarrow \Leftrightarrow Q \Downarrow$.

Definition 3.7. A binary relation \mathcal{R} is *equipollent* if P and Q are equipollent whenever $P \mathcal{R} Q$.

From the point of view of model independence, there is no way to strengthen the equipollence condition. From the point of view of observation, there does not seem to be any room to weaken the condition. It ought to be just right.

3.2 Absolute Equality

The definitions of bisimulation, extensionality, codivergence and equipollence are given without any reference to any model. A straightforward approach is to turn these conditions into the defining properties of a class of relations. Before doing that, the following technical lemma is necessary.

LEMMA 3.8. *If $\{\mathcal{R}_i\}_{i \in I}$ is a family of reflexive, equipollent, extensional, codivergent bisimulations on \mathbb{M} , then $(\bigcup_{i \in I} \mathcal{R}_i)^*$ is a reflexive, equipollent, extensional, codivergent bisimulation.*

PROOF. The bisimulation property is closed under the relational composition. See [Baeten 1996] for the subtlety of this point. \square

It follows that the largest reflexive, equipollent, codivergent, extensional bisimulation of every model of interaction exists. Hence the next definition.

Definition 3.9. The *absolute equality* $=_{\mathbb{M}}$ of \mathbb{M} is the largest relation on $\mathcal{P}_{\mathbb{M}}$ that validates the following statements:

- (1) The relation is reflexive.
- (2) The relation is equipollent, extensional, codivergent and bisimilar.

Definition 3.9 is given in a way that is ready for generalization. An alternative is given in the next lemma.

LEMMA 3.10. *The absolute equality $=_{\mathbb{M}}$ coincides with the largest equipollent, codivergent, closed bisimulation on $\mathcal{P}_{\mathbb{M}}$.*

Since the definition of $=_{\mathbb{M}}$ is model independent, we often omit the subscript.

Using Lemma 3.10 it is easy to derive the following fundamental property of the absolute equality.

LEMMA 3.11. *If $P \Longrightarrow Q$ and $Q \Longrightarrow P$ then $P = Q$.*

PROOF. Suppose $P \equiv P_0 \xrightarrow{\tau} P_1 \xrightarrow{\tau} \dots \xrightarrow{\tau} P_m = Q$ and $Q \equiv Q_0 \xrightarrow{\tau} Q_1 \xrightarrow{\tau} \dots \xrightarrow{\tau} Q_n = P$. Let \mathcal{R} be the relation

$$\{(P_i, Q_j) \mid 0 \leq i \leq m \wedge 0 \leq j \leq n\} \cup =.$$

It is routine to check that \mathcal{R}° is a reflexive, equipollent, extensional, codivergent bisimulation. \square

We shall refer to Lemma 3.11 as *Bisimulation Lemma*. As far as we know, the property described in Lemma 3.11 was discovered by De Nicola et al. [1990], who called it X-property. It is an extremely general result, valid for all the observational equivalences one may think of. We tend to think that Bisimulation Lemma describes an intrinsic property about self evolving systems, it is not a property about system equivalence.

We are now in a position to formally introduce the notion of computation.

- We say that P computes to P' in a single step, notation $P \rightarrow P'$, if $P \xrightarrow{\tau} P' = P$.
- We say that P changes the state to P' in a single step, notation $P \xrightarrow{\iota} P'$, if $P \xrightarrow{\tau} P' \neq P$.

A simple yet fundamental property about computation is stated next.

LEMMA 3.12. *If $P_0 \xrightarrow{\tau} P_1 \xrightarrow{\tau} \dots \xrightarrow{\tau} P_n = P_0$, then $P_0 = P_1 = \dots = P_n$.*

PROOF. Suppose $1 \leq i \leq j \leq n$. Clearly $P_i \Longrightarrow P_j = P_j$ and $P_j \Longrightarrow P_n \Longrightarrow P'_i = P_i$ for some P'_i . It follows immediately from Lemma 3.11 that $P_i = P_j$. \square

Lemma 3.12 will be referred to as *Computation Lemma*. It was discovered by van Glabbeek and Weijland [1989], who termed it Stuttering Lemma. The significance of this lemma lies in that it reveals how systems evolve. All internal action sequences are of the form

$$P_0 \rightarrow^* P'_0 \xrightarrow{\iota} P_1 \rightarrow^* P'_1 \xrightarrow{\iota} \dots P_i \rightarrow^* P'_i \xrightarrow{\iota} P_{i+1} \rightarrow^* \dots \quad (5)$$

After P'_0 has made a change-of-state move to P_1 , there is no turn-back. No later state can ever be equal to P'_0 . In other words, systems evolve in stages. Once a system has reached to a new stage, it will never go back to any of its previous stages. Now if $Q_0 = P_0$ then Q_0 has to simulate (5) by an internal action sequence of the following shape

$$Q_0 \rightarrow^* Q'_0 \xrightarrow{\iota} Q_1 \rightarrow^* Q'_1 \xrightarrow{\iota} \dots Q_i \rightarrow^* Q'_i \xrightarrow{\iota} Q_{i+1} \rightarrow^* \dots \quad (6)$$

such that $Q_1 = P_1, \dots, Q_i = P_i, \dots$. The two internal action sequences (5) and (6) enjoy another interesting property. The corresponding pair P_i, Q_i not only bisimulate into the future, they also bisimulate backwards to history. This *back and forth bisimulation property* was pointed out by De Nicola et al. [1990].

Computation Lemma also points out that as far as the absolute equality is concerned, the codivergence condition is equivalent to the following statement:

If $P_0 = Q_0$ and $P_0 \rightarrow P_1 \rightarrow \dots \rightarrow P_n \dots$ is an infinite computation, then there exists an infinite computation $Q_0 \rightarrow Q_1 \rightarrow \dots \rightarrow Q_n \dots$

So codivergence is a computational property.

To demonstrate the power of the absolute equality we take a look at it in the Computability Model. We remark that since the \mathbb{C} -calculus lacks of the localization operator, the condition (ii) of Definition 3.3 is vacuously met. To begin with we introduce a congruence relation on the \mathbb{C} -processes.

Definition 3.13. The structural congruence $\equiv_{\mathbb{C}}$ is the least equivalent and congruent relation satisfying the following equalities:

$$\begin{aligned} &-\mathbf{0} \mid P \equiv_{\mathbb{C}} P; P \mid Q \equiv_{\mathbb{C}} Q \mid P; (P \mid Q) \mid R \equiv_{\mathbb{C}} P \mid (Q \mid R); \\ &-\Omega \mid \Omega \equiv_{\mathbb{C}} \Omega. \end{aligned}$$

The next result says that $=_{\mathbb{C}}$ is almost the syntactical equality.

THEOREM 3.14. $P =_{\mathbb{C}} Q$ if and only if $P \equiv_{\mathbb{C}} Q$.

PROOF. The main steps of the proof can be structured as follows:

(a) Every \mathbb{C} -process must be of the form

$$\prod_{i \in I} F_{a_i}^{b_i}(\mathbf{h}_i(x)) \mid \prod_{j \in J} \overline{c_j}(\underline{m}_j) \mid \prod_{k \in K} \Omega \mid \prod_{l \in L} \mathbf{0} \quad (7)$$

up to the associativity and commutativity of the composition operator. We say that $F_{a_i}^{b_i}(\mathbf{h}_i(x))$ is a functional component and $\overline{c_j}(\underline{m}_j)$ an output component.

- (b) For each \mathbb{C} -process A there is some \mathbb{C} -process \overline{A} such that $A \mid \overline{A} \Longrightarrow U$ for some unobservable \mathbb{C} -process U .
- (c) If $P \xrightarrow{\tau} P'$ then the number of the output components of P' is no more than that of P .
- (d) For natural numbers $\underline{n}, \underline{m}$, let $\mathbf{f}_{\underline{n} \rightarrow \underline{m}}(x)$ be defined as follows:

$$\mathbf{f}_{\underline{n} \rightarrow \underline{m}}(x) \stackrel{\text{def}}{=} \text{if } x = \underline{n} \text{ then } \underline{m} \text{ else diverge.} \quad (8)$$

Suppose f does not appear in $A \mid B$. Now $A \mid F_a^f(\mathbf{f}_{\underline{n} \rightarrow \underline{n}}(x)) \mid \overline{a}(\underline{n} + 1) \xrightarrow{\tau} A \mid \Omega$. According to (b) there is some \overline{A} such that f does not appear in \overline{A} and

$$\overline{A} \mid A \mid F_a^f(\mathbf{f}_{\underline{n} \rightarrow \underline{n}}(x)) \mid \overline{a}(\underline{n} + 1) \xrightarrow{\tau} \Omega. \quad (9)$$

Now $A \mid F_a^f(\mathbf{f}_{\underline{n} \rightarrow \underline{n}}(x)) \neq B \mid \overline{f}(\underline{n})$ from (9) and the fact that $\overline{A} \mid B \mid \overline{f}(\underline{n}) \mid \overline{a}(\underline{n} + 1)$ is observable.

- (e) Suppose f does not appear in $A \mid B$ and $A \mid \overline{f}(\underline{n}) = B \mid \overline{f}(\underline{n})$. Let g be a name that does not appear in $A \mid B$. The action $A \mid \overline{f}(\underline{n}) \mid F_f^g(\mathbf{f}_{\underline{n} \rightarrow \underline{m}}(x)) \xrightarrow{\tau} A \mid \overline{g}(\underline{m})$ must be bisimulated by $B \mid \overline{f}(\underline{n}) \mid F_f^g(\mathbf{f}_{\underline{n} \rightarrow \underline{m}}(x)) \xrightarrow{\tau} B' \mid \overline{g}(\underline{m})$ due to the property proved in (d). So $B \mid \overline{g}(\underline{m}) \xrightarrow{\tau} B' \mid \overline{g}(\underline{m}) = A \mid \overline{g}(\underline{m})$. By symmetry and the Bisimulation Lemma we conclude that $A \mid \overline{g}(\underline{m}) = B \mid \overline{g}(\underline{m})$.
- (f) Let \mathcal{R} be the following relation

$$\left\{ (A, B) \mid \begin{array}{l} \text{the name } f \text{ does not appear in } A \mid B, \\ \text{and } A \mid \overline{f}(\underline{n}) = B \mid \overline{f}(\underline{n}). \end{array} \right\}.$$

The property proved in (e) implies that \mathcal{R} is closed under composition. It is easily seen that it is also equipollent, codivergent and bisimilar. We conclude that if f does not appear in $A | B$ and $A | \bar{f}(\underline{n}) = B | \bar{f}(\underline{n})$ then $A = B$.

- (g) Suppose f does not appear in $A | B$ and $A | F_a^f(\underline{n} \rightarrow \underline{n})(x) = B | F_a^f(\underline{n} \rightarrow \underline{n})(x)$. It is an easy consequence of (d) that $A | \bar{f}(\underline{n}) = B | \bar{f}(\underline{n})$. Hence $A = B$ by (f).
- (h) Suppose $P \rightarrow^* P_1$ and P_1 may not perform any computation. Let $\bar{a}(\underline{n})$ be an output component of P and f be a name that does not appear in P . The action $P | F_a^f(\underline{n} \rightarrow \underline{n})(x) \xrightarrow{\tau} P' | \bar{f}(\underline{n})$ must be bisimulated by

$$P_1 | F_a^f(\underline{n} \rightarrow \underline{n})(x) \rightarrow^* P_1'' | F_a^f(\underline{n} \rightarrow \underline{n})(x) \xrightarrow{\tau} P_1' | \bar{f}(\underline{n})$$

by (d). According to (g) one has that $P_1 \rightarrow^* P_1''$. And by assumption P_1'' must be P_1 . So $\bar{a}(\underline{n})$ is also an output component of P_1 . In the light of the property stated in (c) we conclude that P and P_1 have the same *multi-set* of the output components.

- (i) Suppose $P =_{\mathbb{C}} Q$, $P \rightarrow^* P_1$, $Q \rightarrow^* Q_1$ and neither P_1 nor Q_1 may perform any computation. Using the idea of (h), we can show that P_1 and Q_1 have the same multi-set of the output components. Consequently P and Q have the same *multi-set* of the output components.
- (j) A consequence of (i) is that $P \neq_{\mathbb{C}} P'$ whenever $P \xrightarrow{\tau} P'$. This is because in every function process $F_a^b(\underline{f}(x))$ the names a, b are distinct.
- (k) Now suppose $P =_{\mathbb{C}} Q$ and the functional components of P are

$$F_{a_1}^{b_1}(\underline{h}_1(x)), \dots, F_{a_k}^{b_k}(\underline{h}_k(x)).$$

Let \underline{m}_1 be a natural number. Then the action

$$P | \bar{a}_1(\underline{m}_1) \xrightarrow{\tau} P_1 \tag{10}$$

must be bisimulated by

$$Q | \bar{a}_1(\underline{m}_1) \xrightarrow{\tau} Q_1. \tag{11}$$

According to (i) the output component $\bar{a}_1(\underline{m}_1)$ must be consumed in the action of (11). It follows that the number of the functional components of Q is no less than k . By symmetry we conclude that P, Q must have the same *number* of the functional components.

- (l) It also follows from (f,i,j) that if $P =_{\mathbb{C}} Q$ and P', Q' are obtained from P, Q by removing the output components then $P' =_{\mathbb{C}} Q'$.
- (m) Suppose $P =_{\mathbb{C}} Q$ and P, Q do not have any output components. Let $F_a^b(\underline{f}(x))$ be a functional component of P . If for every functional component of Q that is of the form $F_a^b(\underline{g}(x))$ the computable function $\underline{g}(x)$ is not the same as $\underline{f}(x)$, then we may force a contradiction by composing with P, Q a number of output \mathbb{C} -processes of the form $\bar{a}(\underline{n})$. So $F_a^b(\underline{f}(x))$ must be a functional component of Q . By symmetry and (k) we conclude that P, Q must have the same *multi-set* of the functional components.

The codivergence property takes care of the Ω components. \square

3.3 Below and Above the Absolute Equality

We provide further evidence in this section that the absolute equality is the only equality for *both* computation and interaction. We do that by taking a look at two modifications of the absolute equality. At the present level of abstraction, there is little room for any refinement on the equipollence, codivergence and extensionality conditions. Moreover since these conditions are proposed as minimal conditions, there is no way to weaken any of them either. Only the bisimulation condition is subject to modification.

Firstly let's think for a while how the bisimulation property can be strengthened. It is not difficult to see that there is only one sensible way to do that.

Definition 3.15. A binary relation \mathcal{R} is a *strong bisimulation* if the following strong bisimulation property holds.

- If $Q\mathcal{R}^{-1}P \xrightarrow{\tau} P'$ then $Q \xrightarrow{\tau} Q'\mathcal{R}^{-1}P'$ for some Q' .
- If $P\mathcal{R}Q \xrightarrow{\tau} Q'$ then $P \xrightarrow{\tau} P'\mathcal{R}Q'$ for some P' .

Obviously the strong bisimulation property subsumes the codivergence property.

Definition 3.16. The *strong equality* $\sim_{\mathbb{M}}$ is the largest reflexive, equipollent, extensional, strong bisimulation on $\mathcal{P}_{\mathbb{M}}$.

For the familiar process calculi, strong equality $\sim_{\mathbb{M}}$ is essentially the strong bisimilarity of Milner [1989a]. It follows from definition that $\sim_{\mathbb{M}} \subseteq =_{\mathbb{M}}$. The strong equality is useful in constructing proof systems [Hennessy and Milner 1985] and in the use of bisimulation-up-to technique [Sangiorgi and Milner 1992]. However from the point of view of the observation theory the requirement that one computation step of a process must be simulated by one computation step of an equal process has serious negative consequences. Church-Turing Thesis would fail under this strong interpretation.

How about weakening the definition of bisimulation? In literature the delay bisimulation [Milner 1981] and the η -bisimulation [Baeten and van Glabbeek 1987] have been proposed as weaker forms of bisimulations. The definitions of these bisimulations must refer to external actions, which is against our model independent philosophy. The least modification of bisimulation is in our view the weak bisimulation of Milner [1989a].

Definition 3.17. A binary relation \mathcal{R} is a *weak bisimulation* if the following *weak bisimulation property* holds.

- If $Q\mathcal{R}^{-1}P \xrightarrow{\tau} P'$ then $Q \Longrightarrow Q'\mathcal{R}^{-1}P'$ for some Q' .
- If $P\mathcal{R}Q \xrightarrow{\tau} Q'$ then $P \Longrightarrow P'\mathcal{R}Q'$ for some P' .

The weak equality given in the next definition is stronger than the weak bisimilarity of Milner in that the former takes divergence into account.

Definition 3.18. The *weak equality* $=_w^{\mathbb{M}}$ is the largest reflexive, equipollent, extensional, codivergent weak bisimulation on $\mathcal{P}_{\mathbb{M}}$.

Clearly $=_{\mathbb{M}} \subseteq =_w^{\mathbb{M}}$. A well known equality valid for $=_w^{\mathbb{M}}$ is the so called Milner's third τ -law, a consequence of which is the following equality

$$\tau.(a+\tau.b) + \tau.c \stackrel{\mathbb{M}}{=} \tau.(a+\tau.b) + \tau.b + \tau.c. \quad (12)$$

Equality (12) is invalid for the absolute equality. The right hand side of (12) has an internal action of the form $\tau.(a+\tau.b) + \tau.b + \tau.c \xrightarrow{\tau} b$. The only way to simulate such an internal action by the left hand is $\tau.(a+\tau.b) + \tau.c \xrightarrow{\tau} a+\tau.b \xrightarrow{\tau} b$. However according to the picture given in (5), these two internal action sequences should never be identified since a single change-of-state action $\tau.(a+\tau.b) + \tau.b + \tau.c \xrightarrow{\tau} b$ is quite different from two consecutive change-of-state actions $\tau.(a+\tau.b) + \tau.c \xrightarrow{\tau} a+\tau.b \xrightarrow{\tau} b$. For another example, consider the π -processes M, A, B defined as follows:

$$\begin{aligned} M &\stackrel{\text{def}}{=} \mu X.a(x).[x=c](\tau.X + \tau.\bar{x}x), \\ A &\stackrel{\text{def}}{=} !M, \\ B &\stackrel{\text{def}}{=} !M \mid a(x).[x=c]\bar{x}x. \end{aligned}$$

It should be clear that $A =_w^\pi B$ but not $A =_\pi B$. The problem of weak equality is that it identifies wrongfully the one-step computations with the change-of-state internal actions.

We have looked at two nearest cousins of the absolute equality. Both are rejectable from the point of view of computation.

3.4 Respectful Operator

An expected criticism to the absolute equality $=_{\mathbb{M}}$ is that it is not necessarily closed under all the operators of \mathbb{M} . Congruence property is so important for an equality that it is tempting to introduce the following definition.

The algebraic \mathbb{M} -equality is the largest reflexive, equipollent, codivergent bisimulation on $\mathcal{P}_{\mathbb{M}}$ closed under all the operators of \mathbb{M} .

One could argue that the above definition is just as model independent as Definition 3.9. Another popular way of enforcing the algebraic property is through the following definition.

P and Q are \mathbb{M} -congruent if the equality $P =_{\mathbb{M}} Q$ is closed under all the operators of \mathbb{M} .

From the point of view of observation theory there are good reasons to reject both definitions. Several arguments are given below.

- (1) If a unary operator op does not preserve the equality $P =_{\mathbb{M}} Q$, then the only explanation is that the operator brings out some difference between P and Q that cannot be observed by any environments. In other words, the operator op injects into the observation theory non-observational distinctions among the processes. Its effect is destructive.
- (2) The requirement that the equality be closed under whatever operator one has in mind is not justifiable in the observation theory. In an interactive framework, one simply cannot grab two pieces of *running* programs by brutal force, put them in a local testing platform, and run the test. Testing for the self evolving processes means that the only thing the testers can do is to interact with the testees, which implies that the testers are the environments in the sense of

Definition 1.1. In the π -calculus for instance a context like $a(x)_{\cdot}$ should not be considered a legitimate environment.

- (3) Algebraic property is not something that can be observed. An observer cannot observe the choice operator of $a.b + b.a$ since the observee may well be $a|b$. The point is that algebraic property has nothing to do with the observation theory. It has everything to do with the semantic definition of the operators. As long as the semantics is right, algebraicity comes for free. Instead of taking algebraicity as a property, we should instead take it as a criterion.

A famous misbehaved operator is the unguarded choice. In order to make a congruence out of the bisimulation equivalence in the presence of this operator, one has to reject $P = \tau.P$. This is ridiculous since the equality between P and $\tau.P$ should never be rejected by any *observational* equality. What should really be rejected is the unguarded choice. The guarded version should always be preferred. Another operator that ought to be rejected is the unrestrained replication. It is clear that $\mathbf{0} =_{\pi} \tau.\mathbf{0}$ but not $!\mathbf{0} =_{\pi} !\tau.\mathbf{0}$. The latter violates the codivergence condition. In retrospect the replicator should have been introduced in its guarded form in the first place. There is really no need for the unrestrained replications since the guarded replications are just as expressive as the unguarded ones.

An operator of \mathbb{M} is said to be *respectful* if it respects the absolute equality $=_{\mathbb{M}}$. Most of the operators introduced in the theory of process calculus are indeed respectful. In present theory, we outlaw any operators that are not respectful.

In Theory of Interaction the absolute equality is a congruence.

So we have imposed another constraint on the models we shall be considering.

3.5 Observational Theory

We now inspect the absolute equality in the models defined in Section 2. It turns out that in each of these models, the absolute equality of two processes can be established using a more tractable method. In such an approach the external actions are explicitly bisimulated. In the cases of \mathbb{VPC} and π , if the codivergence condition is dropped, the explicit characterizations are the branching bisimilarities of van Glabbeek and Weijland [1989]. If moreover the bisimulation is replaced by the weak bisimulation, the explicit characterizations are precisely the weak bisimilarities.

In the following definition and the theorem the model \mathbb{M} can be understood as any of the four models \mathbb{C} , \mathbb{IM} , \mathbb{VPC} , π .

Definition 3.19. An \mathbb{M} -bisimulation \mathcal{R} is a codivergent bisimulation on $\mathcal{P}_{\mathbb{M}}$ that validates the following statements.

- (i) If $Q\mathcal{R}^{-1}P \xrightarrow{\ell} P'$ then $Q \xrightarrow{\ell} Q'\mathcal{R}^{-1}P'$ for some Q' .
- (ii) If $PRQ \xrightarrow{\ell} Q'$ then $P \xrightarrow{\ell} P'\mathcal{R}Q'$ for some P' .

The \mathbb{M} -bisimilarity $\approx_{\mathbb{M}}$ is the largest \mathbb{M} -bisimulation.

We say that (i) and (ii) of the above definition provide an external characterization of the absolute equality $=_{\mathbb{M}}$. We often refer to $\approx_{\mathbb{M}}$ as the *external bisimilarity* for the model \mathbb{M} . The next theorem provides a strong reason for introducing \mathbb{M} -bisimilarities.

THEOREM 3.20. *The following statements are valid.*

- (i) *The external bisimilarity \approx_{VPC} coincides with $=_{\text{VPC}}$.*
- (ii) *The external bisimilarity \approx_{π} coincides with $=_{\pi}$.*

PROOF. First of all we remark that all the three external bisimilarities are congruence. So the inclusions in one direction are easy. (i) The value carried by an output action of a VPC-process can always be recognized unambiguously by some VPC-process that receives it. If say $P =_{\text{VPC}} Q$ and $P \xrightarrow{\bar{a}(\underline{5})} P'$, then it is easy to derive $\exists Q'. Q \xrightarrow{\bar{a}(\underline{5})} Q' =_{\text{VPC}} P'$ using the environment $a(x).if\ x = \underline{5}\ then\ c(z)$, where c appears neither in P nor in Q . (ii) The crucial observation is that

$$\left\{ (P, Q) \left| \begin{array}{l} (a_1, \dots, a_n)(\bar{c}_1 a_1 \mid \dots \mid \bar{c}_n a_n \mid P) =_{\pi} \\ (a_1, \dots, a_n)(\bar{c}_1 a_1 \mid \dots \mid \bar{c}_n a_n \mid Q), \\ \{c_1, \dots, c_n\} \cap gn(P \mid Q) = \emptyset, \ n \geq 0 \end{array} \right. \right\}$$

is a π -bisimulation up to \sim_{π} .

For the complete proofs, the reader is referred to [Fu 2011b; Fu and Zhu 2011]. \square

For the Computability Model it would really be disturbing if the external bisimilarity gives rise to an equality different from the absolute equality. As a matter of fact the coincidence is an immediate consequence of Theorem 3.14.

COROLLARY 3.21. *The external bisimilarity $\approx_{\mathbb{C}}$ coincides with $=_{\mathbb{C}}$.*

Theorem 3.20 and Corollary 3.21 are among a few coincidence results that we know of. However in any event the inclusion $\approx_{\mathbb{M}} \subseteq =_{\mathbb{M}}$ is valid, which is all that matters when using $\approx_{\mathbb{M}}$ to prove process equality.

The external characterization of the absolute equality $=_{\mathbb{M}}$ of a model of interaction \mathbb{M} is the basis for the *observational theory* of \mathbb{M} .

3.6 Unobservable Object

Theory of Interaction brings out the importance of the unobservable objects. The observational theory of these special processes are model independent. It is worthwhile taking a look at them in a model independent fashion. The unobservable objects are computational objects. A close examination of them would reveal to us the rich structure of computation.

The simplest unobservable terminating process is of course $\mathbf{0}$. The simplest unobservable divergent process is

$$\Omega \stackrel{\text{def}}{=} \mu X. \tau.X.$$

The next three are defined in terms of $\mathbf{0}, \Omega$:

$$\begin{aligned} \Delta &\stackrel{\text{def}}{=} \mu X. (\tau.X + \tau.\mathbf{0}), \\ \Gamma &\stackrel{\text{def}}{=} \tau.\mathbf{0} + \tau.\Omega, \\ \Xi &\stackrel{\text{def}}{=} \mu X. (\tau.X + \tau.\mathbf{0} + \tau.\Omega). \end{aligned}$$

Diagrammatically the execution of Δ can be described by the following labeled tree:

where the node indicated by ‘ \bullet ’ is the root of the tree. The object Γ is an internal choice between $\mathbf{0}$ and Ω . Its execution tree is

The execution tree of Ξ is

Using the codivergence condition it should be easy to see that the five processes are pairwise unequal. More unobservable processes can be defined that demonstrate the complex structures of the unobservable processes. In this paper we are content with a construction confirming that the number of the unequal unobservable processes is infinite. Let $\Delta_0, \Delta_1, \Delta_2, \dots$ be defined by the following structural induction:

$$\begin{aligned}
 \Delta_0 &\stackrel{\text{def}}{=} \Delta, \\
 \Delta_1 &\stackrel{\text{def}}{=} \tau.\mathbf{0} + \tau.\Omega + \tau.\Delta_0, \\
 \Delta_2 &\stackrel{\text{def}}{=} \mu X.(\tau.X + \tau.\mathbf{0} + \tau.\Delta_1), \\
 &\vdots \\
 \Delta_{2i+1} &\stackrel{\text{def}}{=} \tau.\mathbf{0} + \tau.\Omega + \tau.\Delta_{2i}, \\
 \Delta_{2i+2} &\stackrel{\text{def}}{=} \mu X.(\tau.X + \tau.\mathbf{0} + \tau.\Delta_{2i+1}), \\
 &\vdots
 \end{aligned}$$

We remark that the infinite sequence $\Delta_0, \Delta_1, \Delta_2, \dots$ converges to a limit as it were.

LEMMA 3.22. $\forall i > 1. \forall j < i. \Delta_j \neq \Delta_i$.

PROOF. The natural induction is as follows:

—First of all $\Delta_1 \neq \Delta_0$. This is because $\Delta_1 \xrightarrow{\iota} \Delta_0$ cannot be matched up by any change-of-state internal action of Δ_0 .

- Suppose $k \leq 2i$. The action $\Delta_{2i+1} \xrightarrow{\iota} \Omega$ cannot be matched up by any action of Δ_k whenever k is even. If k is odd, we apply the induction hypothesis to conclude $\Delta_{2i+1} \neq \Delta_k$. So the process Δ_{2i+1} is not equal to any Δ_k with $k \leq 2i$.
- Suppose $k \leq 2i+1$. The infinite computation caused by $\Delta_{2i+2} \xrightarrow{\tau} \Delta_{2i+2}$ cannot be bisimulated by Δ_k if k is odd. If k is even we may resort to the induction hypothesis. So the process Δ_{2i+2} is not equal to any Δ_k with $k \leq 2i+1$.

We are done. \square

If we fold up the execution tree of Ξ by coercing the equal nodes, we get a finite rooted graph with self-loops. This graph is the simplest representative of the equivalence class of the unobservable processes equal to Ξ . To study the unobservable objects, we may as well focus on these graphs.

Definition 3.23. A directed graph is a *D-graph* if the followings hold:

- (1) There is one and only one node that contains only out-going edges or self-loop. It is the *root* of the *D-graph*.
- (2) There is at most one edge from one node to another. A *self-loop* is an edge from a node to itself.
- (3) Every node is finite branching and is reachable from the root.

The intuition is that every *D-graph*, more precisely the root of the *D-graph*, represents an unobservable object, and a directed edge corresponds to an internal action. A node in a *D-graph* induces a *D-graph* rooted at that node. Using the process theoretical notation, we write $G \xrightarrow{\tau} G'$ if there is an edge from the root of G to the node that induces the *D-graph* G' . Two *D-graphs* G, H are equal, notation $G = H$, if there is a codivergent bisimulation to which the pair $\langle G, H \rangle$ belongs. Two nodes in a *D-graph* are said to be equal if the *D-graphs* induced by them are equal. The *D-graph* is not what we are looking for since there could be too much redundancy in a *D-graph*. Hence the next definition.

Definition 3.24. A *C-graph* is a *D-graph* in which no two nodes are equal.

Given an unobservable process P and a *C-graph* G , we say that G represents P , and P is represented by G , if P and G bisimulate and codiverge. The additional condition imposed in the above definition rules out a node with only one out-going edge. By the Computation Lemma it also rules out any loop with length more than one. So if we remove all the self-loops from a *C-graph*, we obtain a DAG.

LEMMA 3.25. *Two C-graphs are equal if and only if they are isomorphic.*

PROOF. This is a simple induction on the depth of node. \square

We will identify a *C-graph* with the equivalence class of the *C-graphs* isomorphic to it. For each number $i > 0$ let \mathcal{U}_i be the set of the *C-graphs* with i nodes. It is easy to see that \mathcal{U}_1 contains two elements, $\mathbf{0}$ and Ω , and that \mathcal{U}_2 has Δ as its only element. The processes Γ, Ξ are the only elements in \mathcal{U}_3 . Here we confuse for example the notation for the unobservable process Ξ with the notation for the *C-graph* that represents the process.

4. THEORY OF EXPRESSIVENESS

Theory of expressiveness ought to be the most important part of the concurrency theory. It remains however one of the least investigated area in the theory. The lack of a theory of expressiveness has impeded the studies into several important issues. One such study is about operator independence. Given a model \mathbb{M} , the operator independence problem asks if the operators of \mathbb{M} are all independent. Fu and Lu [2010] have shown that all the operators of the π -calculus are independent. This is achieved by studying the expressiveness of every sub-model of the π -calculus obtained by removing one of its operators. Results of this kind are very rare. At the moment we are not even able to say for example that the operators of FA [Fu 2007] are independent to each other. Another branch of investigation heavily depends on the theory of expressiveness is the expressive completeness [Abramsky 2006]. There have been several studies on the problem of Turing completeness of the process calculi. But by and large the results obtained so far are not very conclusive. The lack of a widely acceptable theory of expressiveness is mainly to blame.

The central issue of the theory of expressiveness is to uncover the definition of expressiveness. By definition expressiveness is a relative concept. When we are stating an expressiveness result about a model, we are comparing it against some other model(s). It goes without saying that the ‘being-more-expressive’ relationship has to be transitive, and necessarily model independent. A nontransitive ‘being-more-expressive’ relationship is self-contradictory. An expressive result is often obtained by providing a structural translation, also called an encoding. In this paper we shall maintain a distinction between interpretations and translations/encodings.

- An *interpretation* of \mathbb{M}_0 into \mathbb{M}_1 is a total relation from $\mathcal{P}_{\mathbb{M}_0}$ to $\mathcal{P}_{\mathbb{M}_1}$. This relation interprets a process of \mathbb{M}_0 by a set of processes of \mathbb{M}_1 .
- A *translation/encoding* from \mathbb{M}_0 to \mathbb{M}_1 is an effective function from $\mathcal{P}_{\mathbb{M}_0}$ to $\mathcal{P}_{\mathbb{M}_1}$. A translation/encoding gives rise to an interpretation by composing it with the absolute equality $=_{\mathbb{M}_1}$ of the target model.

An encoding is often defined by a structural induction.

In this section we provide a basic approach to the theory of expressiveness. The philosophy of the approach is that the relative expressiveness relationship must be a generalization of the absolute equality. It is simply inconsistent to apply an expressiveness criterion that is weaker or stronger than the equality to which the expressiveness criterion must refer to.

4.1 Subbisimilarity

An interpretation from \mathbb{M}_0 to \mathbb{M}_1 that formalizes the idea of \mathbb{M}_1 being at least as expressive as \mathbb{M}_0 associates to a process P of \mathbb{M}_0 a set of \mathbb{M}_1 -processes that are equal to P as it were. Such a relation is equipollent, extensional, codivergent and bisimilar. The reflexivity turns into totality and one additional requirement. We now motivate the additional requirement.

There are two dual aspects of the expressive power, the distinguishing power and the control power. They are like the two sides of a coin. If \mathbb{M}_1 is more expressive than \mathbb{M}_0 , then \mathbb{M}_1 should have more distinguishing power than \mathbb{M}_0 . Distinguishing power is about the capacity to interact. It speaks about the ability of the observers.

At the same time, if \mathbb{M}_1 is more expressive than \mathbb{M}_0 , then \mathbb{M}_1 should also have more control power than \mathbb{M}_0 . Control power is about the capacity not to interact. It pronounces the ability of the observees.

Now suppose \mathcal{T} is an interpretation from \mathbb{M}_0 to \mathbb{M}_1 indicating that the latter is at least as expressive as the former. If \mathbb{M}_1 cannot distinguish two processes of \mathbb{M}_0 under the interpretation \mathcal{T} , then according to the above discussion \mathbb{M}_0 cannot distinguish the two processes.

Definition 4.1. The interpretation \mathcal{T} is *complete* if $\mathcal{T}; =_{\mathbb{M}_1}; \mathcal{T}^{-1} \subseteq =_{\mathbb{M}_0}$.

Complementarily if two processes of \mathbb{M}_0 have equal control power to defeat all attempts to distinguish them, then their interpretations under \mathcal{T} should have equal control power to remain indistinguishable.

Definition 4.2. The interpretation is *sound* if $\mathcal{T}^{-1}; =_{\mathbb{M}_0}; \mathcal{T} \subseteq =_{\mathbb{M}_1}$.

We remark that the existence of a universal equality, the absolute equality, is essential to both the completeness and the soundness. An interpretation relating two different equivalences should not be perceived as a relative expressiveness result. Another point is that, since the absolute equality is a special interpretation and an interpretation is a generalization of the absolute equality, the conditions $\mathcal{T}; =_{\mathbb{M}_1}; \mathcal{T}^{-1} \subseteq =_{\mathbb{M}_0}$ and $\mathcal{T}^{-1}; =_{\mathbb{M}_0}; \mathcal{T} \subseteq =_{\mathbb{M}_1}$ are nothing but reflexivity from the point of view of the source model and the target model respectively. This seems to be a good reason for the next definition.

Definition 4.3. An interpretation \mathcal{T} from \mathbb{M}_0 to \mathbb{M}_1 is *fully abstract* if it is both sound and complete.

Following the previous remark, we would like to emphasize the role of the full abstraction by pointing out the following relationship:

Full abstraction is a generalization of reflexivity.

It is easy to see that $\mathcal{T}; =_{\mathbb{M}_1}; \mathcal{T}^{-1} \subseteq =_{\mathbb{M}_0}$ if \mathcal{T} is total, equipollent, extensional, co-divergent and bisimilar. This is why in the following model independent definition, only totality and soundness are required.

Definition 4.4. A relation \mathfrak{R} from \mathbb{M}_0 to \mathbb{M}_1 is a *subbisimilarity*, notation $\mathfrak{R} : \mathbb{M}_0 \rightarrow \mathbb{M}_1$, if it validates the following statements.

- (1) The relation is total and sound.
- (2) The relation is equipollent, extensional, codivergent and bisimilar.

The condition 1 of Definition 4.4 corresponds to the condition 1 of Definition 3.9. It makes sure that the following proposition is valid.

PROPOSITION 4.5. *Subbisimilarities are fully abstract.*

We say that \mathbb{M}_0 is *subbisimilar* to \mathbb{M}_1 , notation $\mathbb{M}_0 \sqsubseteq \mathbb{M}_1$, if there is a subbisimilarity from \mathbb{M}_0 to \mathbb{M}_1 . We write $\mathbb{M}_0 \sqsubset \mathbb{M}_1$ if $\mathbb{M}_0 \sqsubseteq \mathbb{M}_1$ but $\mathbb{M}_1 \not\sqsubseteq \mathbb{M}_0$. The proposition $\mathbb{M}_0 \sqsubseteq \mathbb{M}_1$ can now be reiterated as follows: \mathbb{M}_1 is at least as expressive as \mathbb{M}_0 if for each \mathbb{M}_0 -process P there exists an \mathbb{M}_1 -process Q that is ‘equal’ to P .

PROPOSITION 4.6. *Both \sqsubseteq and \sqsubset are transitive.*

The next simple fact will be used without further reference.

LEMMA 4.7. *Suppose \mathfrak{S} is a subbisimilarity. If $P\mathfrak{S}Q \dashv$ then $P \rightarrow^* P'\mathfrak{S}Q$ for some P' such that $P' \dashv$. Conversely if $Q\mathfrak{S}^{-1}P \dashv$ then $Q \rightarrow^* Q'\mathfrak{S}^{-1}P$ for some Q' such that $Q' \dashv$.*

We can now apply the subbisimilarity tool to the prime models defined in Section 2. The first result assures that the machine model is more elementary than the value passing calculi.

THEOREM 4.8. $\mathbb{IM} \sqsubset \mathbb{VPC}$.

Theorem 4.8 is proved in [Cai and Fu 2010]. The negative result $\mathbb{VPC} \not\sqsubseteq \mathbb{IM}$ is due to the fact that every Interactive Machine \mathbb{M} is essentially of the form $(\tilde{c})(M_1 \mid \dots \mid M_n)$ where M_1, \dots, M_n are Atomic Interactive Machines. This machine may perform at most n immediate actions at a time. It follows that no Interactive Machines can simulate a \mathbb{VPC} interactant which may produce more and more immediate interactive capabilities when it evolves. The negative result does not depend on the output choice operator of \mathbb{VPC} .

COROLLARY 4.9. $\mathbb{VPC}^- \not\sqsubseteq \mathbb{IM}$.

More examples will be given in the following subsections.

The existence of a unique expressiveness relationship helps to formalize many semantic concepts based on expressiveness. Let's see two examples. Suppose op is an operator of \mathbb{M} . Let \mathbb{M}^{-op} be the model obtained from \mathbb{M} by removing op . The independence of op asks if the addition of op to \mathbb{M}^{-op} changes the expressive power of \mathbb{M}^{-op} .

Definition 4.10. An operator op of \mathbb{M} is *independent* if $\mathbb{M} \not\sqsubseteq \mathbb{M}^{-op}$.

Normally we are only concerned with the independence for the operators other than the universal operators. The following fact is established in [Fu and Lu 2010].

FACT 4.11. *The operators of the π -calculus are all independent.*

A related issue asks if an extension is faithful.

Definition 4.12. An operator op of \mathbb{M} is *conservative* if the identity map from \mathbb{M}^{-op} to \mathbb{M} is a subbisimilarity.

Clearly an operator op of \mathbb{M} is conservative if the identity map from \mathbb{M}^{-op} to \mathbb{M} is sound. An explicit characterization of $=_{\mathbb{M}}$ in terms of the external bisimilarity is helpful in deciding if an extension is conservative. The following is an example [Fu and Lu 2010].

FACT 4.13. *Both the match operator and the mismatch operator of the π -calculus are conservative.*

4.2 Soundness and Relative Expressiveness

A relative expressiveness result, say $\mathbb{M} \sqsubseteq \mathbb{N}$, asserts that \mathbb{M} is a submodel of \mathbb{N} ; in other words, the former can be faithfully represented in the latter. Here soundness plays an indispensable role. To get a feeling of the subtlety of the soundness, we take a look at two translations that violate the soundness condition. The purpose

of these exercises is to demonstrate the point that a lot of liberal encodings would be admitted if the soundness condition is dropped.

The first counter example is about a self-translation of the π -calculus. Let $\llbracket _ \rrbracket^\infty$ be a function from \mathcal{P}_π to \mathcal{P}_π that is structural on $\mathbf{0}$, composition, localization, replication, match and mismatch. Its definition on the prefix terms is given by the following clauses.

$$\begin{aligned} \llbracket n(x).T \rrbracket^\infty &\stackrel{\text{def}}{=} \bar{n}(c).c(x).\llbracket T \rrbracket^\infty, \\ \llbracket \bar{m}.T \rrbracket^\infty &\stackrel{\text{def}}{=} n(z).\bar{z}m.\llbracket T \rrbracket^\infty, \text{ where } z \text{ is fresh.} \end{aligned}$$

The next two lemmas describe some standard properties of $\llbracket _ \rrbracket^\infty$.

LEMMA 4.14. *The following statements are valid.*

- (i) *If $T \xrightarrow{\tau} T'$ then $\llbracket T \rrbracket^\infty \xrightarrow{\tau} \llbracket T' \rrbracket^\infty$.*
- (ii) *$\llbracket _ \rrbracket^\infty$ is contained in a minimal extension $\llbracket _ \rrbracket_\downarrow^\infty$ that is equipollent, extensional, codivergent and bisimilar.*

PROOF. The validity of (i) is obvious. In fact $T \xrightarrow{\tau} T'$ implies $\llbracket T \rrbracket^\infty \xrightarrow{\tau} T_c \xrightarrow{\tau} \llbracket T' \rrbracket^\infty$ for some T_c such that $T_c = \llbracket T' \rrbracket^\infty$. The equality tells us how to extend the function $\llbracket _ \rrbracket^\infty$ to a minimal relation $\llbracket _ \rrbracket_\downarrow^\infty$ that is equipollent, extensional, codivergent and bisimilar. \square

LEMMA 4.15. *The composition $=; \{(\llbracket P \rrbracket^\infty, \llbracket Q \rrbracket^\infty) \mid P = Q\}; =$ is equipollent, extensional, codivergent and bisimilar.*

PROOF. Let \mathcal{R} stand for the relation $\{(\llbracket P \rrbracket^\infty, \llbracket Q \rrbracket^\infty) \mid P = Q\}$. Now suppose

$$A' \xleftarrow{l} A = \llbracket P \rrbracket^\infty \mathcal{R} \llbracket Q \rrbracket^\infty = B$$

and that $A \xrightarrow{l} A'$ is simulated by $\llbracket P \rrbracket^\infty \rightarrow^* P_c'' \xrightarrow{l} P_c'$ for some P_c'', P_c' such that $A = P_c''$ and $A' = P_c'$. We may as well assume that $P_c'' \equiv \llbracket P'' \rrbracket^\infty$ for some P'' such that $P \Rightarrow P''$. Now $P'' \xrightarrow{\tau} P'$ for some P' such that $P_c' = \llbracket P' \rrbracket^\infty$. Using the fact $P = Q$, one gets some Q'', Q' such that $Q \Rightarrow Q'' \xrightarrow{\tau} Q' = P'$ and $Q'' = P''$. Therefore $\llbracket Q \rrbracket^\infty \Rightarrow \llbracket Q'' \rrbracket^\infty \xrightarrow{\tau} \llbracket Q' \rrbracket^\infty \mathcal{R} \llbracket P' \rrbracket^\infty$ and $\llbracket Q'' \rrbracket^\infty \mathcal{R} \llbracket P'' \rrbracket^\infty$. Finally some B'', B' exist such that $B \Rightarrow B'' \xrightarrow{\tau} B' = \llbracket Q' \rrbracket^\infty$ and $B'' = \llbracket Q'' \rrbracket^\infty$. What we have essentially demonstrated is that $=; \mathcal{R}; =$ is equipollent, extensional, codivergent and bisimilar. \square

What is missing from Lemma 4.14 and Lemma 4.15? Had we established reflexivity of $=; \mathcal{R}; =$, we would have proved that the composition $\llbracket _ \rrbracket^\infty; =$ were a sub-bisimilarity and that $\llbracket _ \rrbracket^\infty$ were a correct encoding. This is impossible. The map $\llbracket _ \rrbracket^\infty$ fails the soundness condition. The process $!a(x).\bar{b}x$ is equal to the process $(d)(a(x).(\bar{b}x \mid \bar{d}) \mid !d.a(x).(\bar{b}x \mid \bar{d}))$. But the interpretation $\llbracket !a(x).\bar{b}x \rrbracket^\infty$ is obviously unequal to the interpretation $\llbracket (d)(a(x).(\bar{b}x \mid \bar{d}) \mid !d.a(x).(\bar{b}x \mid \bar{d})) \rrbracket^\infty$ since the former can always do input actions at a whereas the latter can only do one such action. We will prove that there is no nontrivial interpretation of the π -calculus into itself.

The second example is more subtle. Suppose we intend to substantiate our intuition that the π -calculus is more powerful than \mathbb{VPC} . After some careful research, we come up with an encoding of \mathbb{VPC} into the π -calculus. It consists of four parts:

- (1) an encoding of the natural numbers by the π -processes;

- (2) an encoding of the boolean expressions by the π -processes;
- (3) an encoding of the term expressions by the π -processes; and
- (4) an encoding of the \mathbb{VPC} -processes by the π -processes.

The encodings are based on an injective map of the term variables onto the name variables. For simplicity we pretend that this map is an identity function. In what follows we will make use of the following encoding of the polyadic prefixes in terms of the monadic prefixes [Milner 1993b]:

$$\begin{aligned} a(x_1, \dots, x_k).T &\stackrel{\text{def}}{=} a(w).w(x_1).\dots.w(x_k).T, \\ \bar{a}\langle n_1, \dots, n_k \rangle.T &\stackrel{\text{def}}{=} \bar{a}(c).\bar{c}n_1.\dots.\bar{c}n_k.T, \\ \bar{a}(b_1, \dots, b_k).T &\stackrel{\text{def}}{=} \bar{a}(c).\bar{c}(b_1).\dots.\bar{c}(b_k).T. \end{aligned}$$

The encoding does not give rise to a subbisimilarity. But it is good for our purpose.

The interpretation of every object in the π -calculus must be accessible. In other words it must let environments know its existence. The natural number \underline{n} will be interpreted as a process that can be visited at a name. So there is an infinite number of interpretations of every natural number, each being accessible at a particular name. The natural numbers can be coded up in many ways. We shall use the following encoding:

$$\begin{aligned} \llbracket 0 \rrbracket_c^\pi &\stackrel{\text{def}}{=} \bar{c}(e, f).\bar{f}, \\ \llbracket n+1 \rrbracket_c^\pi &\stackrel{\text{def}}{=} (d)(\bar{c}(e, f).\bar{e}d \mid \llbracket n \rrbracket_d^\pi). \end{aligned}$$

It is obvious from the definition that $\llbracket i \rrbracket_c^\pi = \llbracket j \rrbracket_c^\pi$ if and only if $i = j$. A process interacts with $\llbracket n \rrbracket_c^\pi$ would have to consume $\llbracket n \rrbracket_c^\pi$ as it were in order to figure out what the number is. Once the process has got the number, it would probably make use of the number several times. For that to be possible, the process must make several copies of the number. A better approach is to introduce an operation that duplicates the encoded natural number for a potentially infinite number of times. To describe the operation it is convenient to introduce the following persistent form of the encoding:

$$\begin{aligned} \llbracket !0 \rrbracket_c^\pi &\stackrel{\text{def}}{=} !\bar{c}(e, f).\bar{f}, \\ \llbracket !n+1 \rrbracket_c^\pi &\stackrel{\text{def}}{=} (d)(!\bar{c}(e, f).\bar{e}d \mid \llbracket !n \rrbracket_d^\pi). \end{aligned}$$

Now for every π -term T , we would like to introduce a π -term $Rep(x, u).T$ that replicates an input number. Operationally it satisfies the following computational property:

$$\llbracket n \rrbracket_c^\pi \mid Rep(c, d).T \xrightarrow{\tau} \llbracket !n \rrbracket_d^\pi \mid T. \quad (13)$$

We may define $Rep(x, u).T$ by the following term

$$\begin{aligned} (fg)(x(y, z).(z.(T \mid !\bar{u}(e, f).\bar{f}) \mid y(x).(d)\bar{f}\langle d, x \rangle.g.!\bar{u}(e, f).\bar{e}d) \\ \mid !\bar{f}(v, x).x(y, z).(z.\bar{g}.(T \mid !\bar{v}(e, f).\bar{f}) \mid y(x).(d)\bar{f}\langle d, x \rangle.!\bar{v}(e, f).\bar{e}d)). \end{aligned}$$

The term $Rep(c, d).T$ transforms the encoding $\llbracket n \rrbracket_c^\pi$ into a replicated form before T can be fired. The name g is used to prevent the replicated form from being used

before it is completely generated. Once we have the process $\llbracket !n \rrbracket_c^\pi$ we might want to make a copy of it whenever necessary. This is done by $Copy(x, u).T$ that is defined by the following term

$$(fg)(x(y, z).(z.(T | \bar{u}(e, f).\bar{f}) | y(x).(d)\bar{f}\langle d, x \rangle.g.\bar{u}(e, f).\bar{e}d) | !f(v, x).x(y, z).(z.\bar{g}.(T | \bar{v}(e, f).\bar{f}) | y(x).(d)\bar{f}\langle d, x \rangle.\bar{v}(e, f).\bar{e}d)).$$

It is clear that the following computations are admissible.

$$\begin{aligned} \llbracket n \rrbracket_c^\pi | Copy(c, d).T &\xrightarrow{\tau} \llbracket n \rrbracket_d^\pi | T, \\ \llbracket !n \rrbracket_c^\pi | Copy(c, d).T &\xrightarrow{\tau} \llbracket !n \rrbracket_c^\pi | \llbracket n \rrbracket_d^\pi | T. \end{aligned}$$

The encoding of the boolean expressions explores the fact that when a process reaches to a state where a conditional subterm is in a fireable position, its free variables must have all been instantiated. The structural definition of the encoding is as follows:

$$\begin{aligned} \llbracket \top \rrbracket_c^\pi &\stackrel{\text{def}}{=} \bar{c}(e, f).\bar{e}, \\ \llbracket \perp \rrbracket_c^\pi &\stackrel{\text{def}}{=} \bar{c}(e, f).\bar{f}, \\ \llbracket p=q \rrbracket_c^\pi &\stackrel{\text{def}}{=} Equal(p, q, c), \\ \llbracket p < q \rrbracket_c^\pi &\stackrel{\text{def}}{=} Less(p, q, c), \\ \llbracket \neg\varphi \rrbracket_c^\pi &\stackrel{\text{def}}{=} (d)(\llbracket \varphi \rrbracket_d^\pi | d(u, v).(u.\llbracket \perp \rrbracket_c^\pi | v.\llbracket \top \rrbracket_c^\pi)), \\ \llbracket \varphi \wedge \psi \rrbracket_c^\pi &\stackrel{\text{def}}{=} (d_1 d_2)(\llbracket \varphi \rrbracket_{d_1}^\pi | \llbracket \psi \rrbracket_{d_2}^\pi | d_1(u, v).d_2(u', v').(u.u'.\llbracket \top \rrbracket_c^\pi | u.v'.\llbracket \perp \rrbracket_c^\pi | v.u'.\llbracket \perp \rrbracket_c^\pi | v.v'.\llbracket \perp \rrbracket_c^\pi)), \\ \llbracket \varphi \vee \psi \rrbracket_c^\pi &\stackrel{\text{def}}{=} (d_1 d_2)(\llbracket \varphi \rrbracket_{d_1}^\pi | \llbracket \psi \rrbracket_{d_2}^\pi | d_1(u, v).d_2(u', v').(u.u'.\llbracket \top \rrbracket_c^\pi | u.v'.\llbracket \top \rrbracket_c^\pi | v.u'.\llbracket \top \rrbracket_c^\pi | v.v'.\llbracket \perp \rrbracket_c^\pi)). \end{aligned}$$

The processes $Equal(p, q, c)$ and $Less(p, q, c)$ appeared in the above encoding are defined as follows:

$$\begin{aligned} Equal(p, q, c) &\stackrel{\text{def}}{=} (d)(\bar{d}\langle p, q \rangle | !d(u, v).u(x, y).v(x', y').(x(w).x'(w').\bar{d}\langle w, w' \rangle | y.x'(w').\llbracket \perp \rrbracket_c^\pi | x(w).y'.\llbracket \perp \rrbracket_c^\pi | y.y'.\llbracket \top \rrbracket_c^\pi)), \\ Less(p, q, c) &\stackrel{\text{def}}{=} (d)(\bar{d}\langle p, q \rangle | !d(u, v).u(x, y).v(x', y').(x(w).x'(w').\bar{d}\langle w, w' \rangle | y.x'(w').\llbracket \top \rrbracket_c^\pi | x(w).y'.\llbracket \perp \rrbracket_c^\pi | y.y'.\llbracket \perp \rrbracket_c^\pi)). \end{aligned}$$

The correctness of the encoding $\llbracket \varphi \rrbracket_c^\pi$ is stated in the next lemma.

LEMMA 4.16. *Let x_1, \dots, x_i be the variables in φ . Then $\vdash \varphi\{n_1/x_1, \dots, n_i/x_i\}$ if and only if $(c_1 \dots c_i)(\llbracket \varphi \rrbracket_c^\pi \{c_1/x_1, \dots, c_i/x_i\} | \llbracket n_1 \rrbracket_{c_1}^\pi | \dots | \llbracket n_i \rrbracket_{c_i}^\pi) = \llbracket \top \rrbracket_c^\pi$.*

The encoding of the term expressions is straightforward, using the fact that a term expression is either a natural number, or a term variable, or of the form $\underline{i+x}$.

$$\llbracket t \rrbracket_c^\pi \stackrel{\text{def}}{=} \begin{cases} \llbracket \underline{i} \rrbracket_c^\pi, & \text{if } t = \underline{i}, \\ Copy(x, c), & \text{if } t = x, \\ (c_1 \dots c_i)Copy(x, c_i).(\bar{c}c_1 | \bar{c}_1 c_2 | \dots | \bar{c}_{i-1} c_i), & \text{if } t = \underline{i+x}. \end{cases}$$

Finally we can define the encoding of the \mathbb{VPC} -processes. The translation is defined by the following induction:

$$\begin{aligned} \llbracket \sum_{1 \leq i \leq k} a(x).T_i \rrbracket^{vpc \rightarrow \pi} &\stackrel{\text{def}}{=} \sum_{1 \leq i \leq k} a(x).(c)Rep(x, c).\llbracket T_i \rrbracket^{vpc \rightarrow \pi} \{c/x\}, \\ \llbracket \sum_{1 \leq i \leq k} \bar{a}(t_i).T_i \rrbracket^{vpc \rightarrow \pi} &\stackrel{\text{def}}{=} \sum_{1 \leq i \leq k} \bar{a}(c).(\llbracket t_i \rrbracket_c^\pi \mid \llbracket T_i \rrbracket^{vpc \rightarrow \pi}), \\ \llbracket \text{if } \varphi \text{ then } T \rrbracket^{vpc \rightarrow \pi} &\stackrel{\text{def}}{=} (c)(\llbracket \varphi \rrbracket_c^\pi \mid c(u, v).u.\llbracket T \rrbracket^{vpc \rightarrow \pi}), \\ \llbracket !a(x).T \rrbracket^{vpc \rightarrow \pi} &\stackrel{\text{def}}{=} !a(x).(c)Rep(x, c).\llbracket T \rrbracket^{vpc \rightarrow \pi} \{c/x\}, \\ \llbracket !\bar{a}(t).T \rrbracket^{vpc \rightarrow \pi} &\stackrel{\text{def}}{=} !\bar{a}(c).(\llbracket t \rrbracket_c^\pi \mid \llbracket T \rrbracket^{vpc \rightarrow \pi}). \end{aligned}$$

Compared to the map $\llbracket _ \rrbracket^\times$, the translation $\llbracket _ \rrbracket^{vpc \rightarrow \pi}$ is much better. We will not go into details to demonstrate how this encoding satisfies the good properties stated in the next lemma. It suffices to say that the long proof is routine.

LEMMA 4.17. *The composition $\llbracket _ \rrbracket^{vpc \rightarrow \pi}; =_\pi$ is equipollent, extensional, codivergent and bisimilar.*

Lemma 4.17 should not be overvalued since $\llbracket _ \rrbracket^{vpc \rightarrow \pi}; =_\pi$ fails to be sound. We shall prove this claim in the next section.

4.3 Incompatibility of VPC and Π

We report in this section the expressiveness results obtained by applying the sub-bisimilarity tool to \mathbb{VPC} and π . The first result confirms that the object oriented programming style is very different from the functional programming style.

PROPOSITION 4.18. $\pi \not\sqsubseteq \mathbb{VPC}$.

PROOF. It suffices to show that the π -process $a(x).\bar{x}$ cannot be simulated by any \mathbb{VPC} -process. Assume that there were a subbisimilarity \mathfrak{F} from π to \mathbb{VPC} . Let A and A_b be such that $a(x).\bar{x} \mathfrak{F} A$ and $\bar{a}b \mathfrak{F} A_b$. It is easy to see that after A_b has done an external action at the name a it becomes some process equal to $\mathbf{0}$. Now A may contain only a finite number of global names. So its interactions with the interpretations of $\bar{a}b_1, \dots, \bar{a}b_k, \dots$ cannot be all correct. \square

The second result reveals that the value-passing mechanism of the functional programming is beyond the communication capacity of the object oriented programming.

THEOREM 4.19. $\mathbb{VPC} \not\sqsubseteq \pi$.

PROOF. Assume that there were a subbisimilarity \mathfrak{G} from \mathbb{VPC} to π . For each name a and each natural number i , let $[\dot{i}]_a \rightarrow$ be a chosen interpretation of $\bar{a}(\dot{i})$ under \mathfrak{G} and $A \rightarrow$ be a chosen interpretation of $a(x)$ by \mathfrak{G} . Before proving the theorem, we need to derive a number of necessary properties about \dot{i} and A .

—By codivergence there is no infinite internal action sequence from $[\dot{i}]_a \mid A$. According to König Lemma there are only a finite number of internal action sequences from $[\dot{i}]_a \mid A$. Every internal action sequence of $[\dot{i}]_a \mid A$ terminates in a process equal to $\mathbf{0}$.

- If $[\underline{i}]_a | A \xrightarrow{\tau} B$ then $[\underline{i}]_a | A \neq B$. This is proved by showing that there is a sequence of external actions of $[\underline{i}]_a | A$ that contains strictly more external actions at a than any external action sequence from B .
- It follows from the previous fact that the action $\bar{a}(\underline{i}) | a(x) \xrightarrow{\iota} =_{\pi} \mathbf{0}$ must be matched up by every immediate tau action of $[\underline{i}]_a | A$ and that $[\underline{i}]_a | A \xrightarrow{\iota} B =_{\pi} \mathbf{0}$ whenever $[\underline{i}]_a | A \xrightarrow{\tau} B$.
- The process $[\underline{i}]_a$ may perform either an input action at a or an output action at a . It cannot perform both an input action and an output action for otherwise $[\underline{i}]_a | [\underline{i}]_a$ would be able to perform a change-of-state internal action.
- If $[\underline{i}]_a$ may perform an input (output) action at a , then for every j the process $[\underline{j}]_a$ may perform an input (output) action.
- If $i \neq j$ and $[\underline{i}]_a \xrightarrow{\bar{a}b} A$ and $[\underline{j}]_a \xrightarrow{\bar{a}b'} A'$, then b and b' must be distinct names. This can be proved by exploiting the property of B , where the π -process B is such that $a(x).\bar{a}(x) \mathfrak{G} B \dashv$.

There are two cases according to the type of the external actions of $[\underline{i}]_a$.

- The immediate actions of $[\underline{i}]_a$ are output actions. There are two subcases.
 - (1) There are two distinct natural numbers $\underline{j}, \underline{k}$ such that both $[\underline{j}]_a$ and $[\underline{k}]_a$ can perform bound output actions. Suppose

$$\begin{aligned} [\underline{j}]_a &\xrightarrow{\bar{a}(b)} J, \\ [\underline{k}]_a &\xrightarrow{\bar{a}(b)} K. \end{aligned}$$

Consider the VPC-processes defined as follows:

$$\begin{aligned} C_d &\stackrel{\text{def}}{=} !a(x).\bar{d}(x), \\ C_e &\stackrel{\text{def}}{=} !a(x).\bar{e}(x), \\ C_j &\stackrel{\text{def}}{=} a(x).\text{if } x = \underline{j} \text{ then } \bar{d}(x) \text{ else } \bar{e}(x). \end{aligned}$$

It is easily seen that $C_d | C_e = C_d | C_e | C_j$. Let D_d, D_e, D_j be the π -processes such that $C_d \mathfrak{G} D_d \dashv$, $C_e \mathfrak{G} D_e \dashv$ and $C_j \mathfrak{G} D_j \dashv$. By extensionality and soundness one has that $D_d | D_e = D_d | D_e | D_j$ and that D_d, D_e, D_j can only do input actions at a . Further properties about D_d, D_e, D_j are stated as follows:

- $D_e | [\underline{j}]_a \xrightarrow{\iota} D'_e$ for some D'_e such that D'_e may only perform external actions at a and e . Notice that D'_e may not perform any output action at a due to the fact that D'_e cannot do a change-of-state internal action.
 - $D_j | [\underline{j}]_a \xrightarrow{\iota} D'_j$ for some D'_j such that D'_j may only perform actions at d .
- Now suppose $D_d \xrightarrow{ab} D'_d$, $D_e \xrightarrow{ab} D'_e$ and $D_j \xrightarrow{ab} D'_j$. Without loss of generality we may assume that $D_d | D_e | D_j \xrightarrow{ab} D_d | D_e | D'_j$ is simulated by $D_d | D_e \xrightarrow{ab} D_d | D'_e$. We would then have the following equality

$$(a)(e)(b)(D_d | D'_e | J) = (a)(e)(b)(D_d | D_e | D'_j | J). \quad (14)$$

This is a contradiction since the right hand side of (14) is observable whereas the left hand side is unobservable.

- (2) Suppose that almost all members of $\{\llbracket 0 \rrbracket_a, \llbracket 1 \rrbracket_a, \llbracket 2 \rrbracket_a, \dots\}$ can perform free output actions. Let O be an interpretation of the following \mathbb{VPC} -process

$$a(z).if\ z\ is\ even\ then\ \bar{f}(z+1)\ else\ diverge.$$

For each natural number i , we have the following interaction

$$\llbracket 2i \rrbracket_a \mid O \xrightarrow{!} \llbracket 2i+1 \rrbracket_f. \quad (15)$$

What is described in (15) renders a contradiction since O may contain only a finite number of global names and the set of the global names released at f by the processes in $\{\llbracket 2 \rrbracket_f, \llbracket 4 \rrbracket_f, \dots\}$ is disjoint from those released by the processes in $\{\llbracket 1 \rrbracket_f, \llbracket 3 \rrbracket_f, \llbracket 5 \rrbracket_f, \dots\}$.

—Now suppose the immediate actions of $\llbracket i \rrbracket_a$ are input actions. Then the processes D_d, D_e, D_j defined in the previous case would have to do output actions. A contradiction can be similarly derived. So this case is also impossible.

We conclude that $\mathbb{VPC} \not\sqsubseteq \pi$. \square

4.4 Self Interpretation

An obvious consequence of Definition 4.4 is that there could be many subbisimilarities from one model to another. Why don't we focus on the 'largest subbisimilarity' between two models? The results in this section will tell us that we really should not do that. Before proving these results we need to introduce some terminologies.

Definition 4.20. Two subbisimilarities $\mathfrak{R}, \mathfrak{R}' : \mathbb{M} \rightarrow \mathbb{N}$ are *incompatible* if there is some $P \in \mathcal{P}_{\mathbb{M}}$ such that $Q \neq O$ whenever $P\mathfrak{R}Q$ and $P\mathfrak{R}'O$. They are *compatible* if they are not incompatible. A subbisimilarity $\mathfrak{R} : \mathbb{M} \rightarrow \mathbb{N}$ is *maximal* if $\mathfrak{R}' \subseteq \mathfrak{R}$ whenever $\mathfrak{R}' : \mathbb{M} \rightarrow \mathbb{N}$ is compatible with \mathfrak{R} .

Every subbisimilarity \mathfrak{R} is contained in the maximal subbisimilarity $\mathfrak{R}; =$. Two compatible subbisimilarities are essentially the same interpretation. So we may as well identify a subbisimilarity \mathfrak{R} with the maximal subbisimilarity $\mathfrak{R}; =$. We say that there is a unique interpretation from \mathbb{M} to \mathbb{N} if all the subbisimilarities from \mathbb{M} to \mathbb{N} are compatible; in other words, the largest subbisimilarity from \mathbb{M} to \mathbb{N} exists. The largest subbisimilarity from \mathbb{M} to itself is essentially the absolute equality on the model \mathbb{M} . In the rest of this section we inspect the self interpretations on the three prime models.

PROPOSITION 4.21. *There are an infinite number of pairwise incompatible subbisimilarities from \mathbb{VPC} to \mathbb{VPC} .*

PROOF. Suppose f is a bijective computable function. Clearly its inverse function f^{-1} is also a bijective computable function. We may think of f as an encoding function and f^{-1} the corresponding decoding function. A relation $\llbracket _ \rrbracket^f$ from \mathbb{VPC} to \mathbb{VPC} can be defined that makes use of the encoding and decoding functions. The encoding of the choice terms is defined as follows:

$$\begin{aligned} \llbracket \sum_{1 \leq i \leq k} a(x).T_i \rrbracket^f &\stackrel{\text{def}}{=} \sum_{1 \leq i \leq k} a(u).(c)((b)(\bar{b}(u) \mid F_b^c(f^{-1})) \mid c(x).\llbracket T_i \rrbracket^f), \\ \llbracket \sum_{1 \leq i \leq k} \bar{a}(t_i).T_i \rrbracket^f &\stackrel{\text{def}}{=} (\tilde{c})(\prod_{1 \leq i \leq k} (b)(\bar{b}(t_i) \mid F_b^{c_i}(f)) \mid c_1(z_1) \dots c_k(z_k). \sum_{1 \leq i \leq k} \bar{a}(z_i).\llbracket T_i \rrbracket^f), \end{aligned}$$

where c is a fresh name. In the above encoding, $F_b^c(f^{-1})$ is the \mathbb{VPC} -process that after inputting a natural number at b , say \underline{n} , calculates $f^{-1}(\underline{n})$ before delivering the result at c . The process $F_b^{c_i}(f)$ is similar. The precise definition of $F_b^c(\cdot)$ is given in [Fu 2011b]. The replication terms can be interpreted in the same fashion. It is not difficult to see that $\llbracket \cdot \rrbracket^f; =_{\mathbb{VPC}}$ is a subbisimilarity from \mathbb{VPC} to \mathbb{VPC} . \square

\mathbb{VPC} is an interactive version of the recursion theory. The above proposition implies that if the recursion theory can be embedded into a model of interaction, it can be embedded in an infinite number of ways.

Using the same idea it is routine to establish the next proposition.

PROPOSITION 4.22. *There are an infinite number of pairwise incompatible subbisimilarities from \mathbb{IM} to \mathbb{IM} .*

We have seen that generally models of interaction admit multiple self interpretations. It would be nice to see a model on which the only self interpretation is the trivial one.

THEOREM 4.23. *The absolute equality is the largest subbisimilarity from π to π .*

PROOF. Suppose \sqsubseteq_π is a maximal subbisimilarity from π to π . We shall show that \sqsubseteq_π is a π -bisimulation. To start with we need to derive a number of properties about the interpretation \sqsubseteq_π .

(1) First of all we prove that the process $\bar{a}c$ is interpreted by itself. The following arguments resemble those in the proof of Theorem 4.19.

- (a) Let A be such that $a(x) \sqsubseteq_\pi A \not\rightarrow$. The process A may not do both an input action and an output action at the name a . Suppose otherwise. Then $A | A$ would be able to do an internal action, say $A | A \xrightarrow{\tau} A_1$. By extensionality this internal action may be caused either by $A \xrightarrow{\bar{a}(c)}$ and $A \xrightarrow{ac}$, or by $A \xrightarrow{\bar{a}a}$ and $A \xrightarrow{aa}$. Assume $A | A = A_1$. In the first case $A | A \xrightarrow{\bar{a}(c_1)ac_1} A'_1$ must be matched up by $A_1 \xrightarrow{* \bar{a}(c_1)ac_1} A_2 = A'_1$ for some A_2 , where the two external actions at a may induce an interaction. Now $A'_1 \xrightarrow{* \bar{a}(c_1)ac_1} A'_2$ must also be simulated by A_2 . Continuing in this way we get an infinite action sequence

$$A | A \xrightarrow{\bar{a}(c_1)ac_1} \rightarrow * \bar{a}(c_2)ac_2 \rightarrow * \bar{a}(c_3)ac_3 \rightarrow \dots \quad (16)$$

It follows from (16) that $A | A$ would be able to do an infinite sequence of internal actions, which would violate the codivergence property. The same contradiction can be derived if $A | A \xrightarrow{\tau} A_1$ was caused by $A \xrightarrow{\bar{a}a}$ and $A \xrightarrow{aa}$. So the assumption $A | A = A_1$ was wrong. However the change-of-state internal action $A | A \xrightarrow{\iota} A_1$ also renders a contradiction since $a(x) | a(x)$ cannot do any change of state internal action. So A may perform either input actions at a or output actions at a ; it cannot do both input and output actions at a .

- (b) For each c , let \bar{A}_c be such that $\bar{a}c \sqsubseteq_\pi \bar{A}_c \not\rightarrow$. By codivergence the set of the internal action sequences of $A | \bar{A}_c$ form a finite tree. It follows that the

longest external action sequence cannot be bisimulated by any A' satisfying $A | \bar{A}_c \xrightarrow{\tau} A'$. So $A | \bar{A}_c \xrightarrow{l} A' = \mathbf{0}$ whenever $A | \bar{A}_c \xrightarrow{\tau} A'$.

- (c) If \bar{A}_c can do an input (output) action then \bar{A}_f can do an input (output) action for all f , where \bar{A}_f is such that $\bar{a}f \sqsubseteq_{\pi} \bar{A}_f \not\rightarrow$.
- (d) Let C_d, C_e, C_v be defined as follows:

$$\begin{aligned} C_d &\stackrel{\text{def}}{=} !a(x).\bar{d}x, \\ C_e &\stackrel{\text{def}}{=} !a(x).\bar{e}x, \\ C_v &\stackrel{\text{def}}{=} a(x).([x=c]\bar{d}x \mid [x \neq c]\bar{e}x). \end{aligned}$$

Let D_d, D_e, D_v be the π -processes such that $C_d \sqsubseteq_{\pi} D_d \not\rightarrow$, $C_e \sqsubseteq_{\pi} D_e \not\rightarrow$ and $C_v \sqsubseteq_{\pi} D_v \not\rightarrow$. By extensionality and soundness the equality

$$D_d \mid D_e = D_d \mid D_e \mid D_v \quad (17)$$

follows from the equality $C_d \mid C_e = C_d \mid C_e \mid C_v$.

- (e) Suppose D_v could do an output action, say $D_v \xrightarrow{\lambda} D'_v$. Then \bar{A}_f may only do input actions at a , and consequently D_d, D_e may only do output actions at a . Using the fact that the τ -tree of $D_d \mid \bar{A}_f$ is finite, it is easy to see that every internal action $D_d \mid \bar{A}_f \xrightarrow{\tau} G$ is a change-of-state action that necessarily bisimulates $!a(x).\bar{d}x \mid \bar{a}f \xrightarrow{\tau} !a(x).\bar{d}x \mid \bar{d}f$. Moreover G may not perform any input action at the name a . These remarks also apply to D_e .
- (f) It follows from (17) that the action must be bisimulated by either D_d or D_e . Without loss of generality assume that $D_d \xrightarrow{\lambda} D'_d$ such that $D'_d \mid D_e = D_d \mid D_e \mid D'_v$. Suppose $\bar{A}_f \xrightarrow{\lambda'} \bar{A}'_f$ for some input action λ' that is complementary to λ . Let $\bar{A}_f \mid D_d \xrightarrow{\tau} A'$ be the interaction induced by $\bar{A}_f \xrightarrow{\lambda'} \bar{A}'_f$ and $D_d \xrightarrow{\lambda} D'_d$, and $\bar{A}_f \mid D_v \xrightarrow{\tau} A''$ be induced by $\bar{A}_f \xrightarrow{\lambda'} \bar{A}'_f$ and $D_v \xrightarrow{\lambda} D'_v$. Clearly we must have

$$A' \mid D_e = D_d \mid D_e \mid A''. \quad (18)$$

According to property (e), the processes A' and D_e may not interact. Similarly A'' and $D_d \mid D_e$ may not interact. It follows that the equality (18) renders a contradiction since $(a)(e)(A' \mid D_e)$ is observable whereas $(a)(e)(D_d \mid D_e \mid A'')$ is not observable. We conclude that D_d, D_e, D_v can only perform input action(s) at a . Accordingly for each c , the process \bar{A}_c can only do output action(s) at a .

- (g) Suppose that there existed some \bar{A}_g that could do a bound output action, say $\bar{A}_g \xrightarrow{a(d')}$. Now if \bar{A}_h could also do a bound output action, then by α -convention we may assume that $\bar{A}_g \xrightarrow{a(d'')}$ and $\bar{A}_h \xrightarrow{a(d'')}$ for some fresh d'' . If \bar{A}_h performs a free output action, the output action must be $\bar{a}h$ according to (h). By extensionality we may assume that h does not appear as a global name in \bar{A}_g . Thus $\bar{A}_g \xrightarrow{a(h)}$ by α -conversion. In either case we may repeat the argument in (f) to derive a contradiction.

- (h) We conclude that, for all c , the process \bar{A}_c can only do free output action(s). Since $A | \bar{A}_c \xrightarrow{\tau} \mathbf{0}$, it must be the case that $\bar{A}_c \xrightarrow{\bar{a}c'} \mathbf{0}$ for some c' . Now let J_a be a process such that $a(x).\bar{x} \sqsubseteq_{\pi} J_a \dashv$. By extensionality we may assume that a is the only global name that appears in J_a . The action $a(x).\bar{x} | \bar{a}c \xrightarrow{\iota} \bar{c}$ must be matched up by $J_a | \bar{A}_c \xrightarrow{\iota} \bar{C}_c$ such that \bar{C}_c is observable at c . So c' must be c .

What we have proved is that $\bar{a}c \sqsubseteq_{\pi} \bar{a}c$ for all a, c .

- (2) The above argument can be repeated to show that a process of the form $\bar{a}c + \bar{a}d$ is interpreted by itself.
- (3) Let Q be such that $a(x).[x \neq c]e + a(x).d \sqsubseteq_{\pi} Q \dashv$. The following properties hold by the result of (2) and extensionality:

- (a) $Q \xrightarrow{ag} \rightarrow^* \xrightarrow{dh} \mathbf{0}$ for all g and all h ;
- (b) $Q \xrightarrow{ag} \rightarrow^* \xrightarrow{eh} \mathbf{0}$ for every name $g \neq c$ and every h .

We conclude by Theorem 3.20 that $Q = a(x).[x \neq c]e + a(x).d$. In other words $a(x).[x \neq c]e + a(x).d \sqsubseteq_{\pi} a(x).[x \neq c]e + a(x).d$.

- (4) Using the fact that processes of the form $\bar{a}c + \bar{a}d$ and $a(x).[x \neq c]e + a(x).d$ are interpreted by themselves, it is standard to prove the following properties for all P, Q such that $P \sqsubseteq_{\pi} Q$:

- If $P \xrightarrow{ac} P'$ then $Q \xrightarrow{ac} Q'$ and $P' \sqsubseteq_{\pi} Q'$.
- If $Q \xrightarrow{ac} Q'$ then $P \xrightarrow{ac} P'$ and $P' \sqsubseteq_{\pi} Q'$.
- If $P \xrightarrow{\bar{a}c} P'$ then $Q \xrightarrow{\bar{a}c} Q'$ and $P' \sqsubseteq_{\pi} Q'$.
- If $Q \xrightarrow{\bar{a}c} Q'$ then $P \xrightarrow{\bar{a}c} P'$ and $P' \sqsubseteq_{\pi} Q'$.

- (5) Suppose F contains neither the replication operator nor the localization operator. Let G be such that $F \sqsubseteq_{\pi} G$. Assume that $G \xrightarrow{\lambda_1} \dots \xrightarrow{\lambda_k} G' \xrightarrow{\bar{a}(c)} G''$ for some G', G'' , where $\lambda_1, \dots, \lambda_k$ are either input actions or free output actions. Using observers discussed in (2) and (3), one may force F to perform the action sequence $F \xrightarrow{\lambda_1} \dots \xrightarrow{\lambda_k} F'$ such that $F' \sqsubseteq_{\pi} G'$. As in the proof of (3) one can argue that, for fresh d, e , the process $a(x).[x \notin gn(F' | G')]e + a(x).d$ is interpreted by itself. But then $F' | (a(x).[x \notin gn(F' | G')]e + a(x).d) \sqsubseteq_{\pi} G' | (a(x).[x \notin gn(F' | G')]e + a(x).d)$ renders a contradiction. We conclude that G may never perform any bound output action.

- (6) It follows from (4) and (5) that the following relation

$$\{(F, G) \mid F \sqsubseteq_{\pi} G, \text{ and } F \text{ contains neither replication nor localization}\}$$

is an external bisimulation. So every π -process that contains neither the replication operator nor the localization operator is interpreted by itself under \sqsubseteq_{π} .

The importance of property (6) is that it allows one to repeat the proof of Theorem 3.20 to show that \sqsubseteq_{π} is an external bisimulation. Therefore $\sqsubseteq_{\pi} \subseteq =_{\pi}$. The coincidence between \sqsubseteq_{π} and $=_{\pi}$ follows by the maximality of \sqsubseteq_{π} . In other words, the absolute equality on π is the only interpretation from π to π . \square

4.5 Subbisimilarity for Pi Variant

The choice operator we have used in this paper is weaker than the choice operators one encounters in literature. Apart from the general unguarded choice operator [Milner 1989a], the mixed choice (or guarded choice) and the separated choice are sufficient in many applications [Palamidessi 2003; Fu and Lu 2010]. Further variants of the π -calculus can be obtained by replacing the replication operator by the fixpoint operator or parametric definition. Altogether we have nine variants of the π -calculus. See [Fu and Lu 2010] for detailed description.

We are interested in the relative expressive power of the nine variants. Since the action sets of the variants are all the same, we could try an external characterization of the subbisimilarity.

Definition 4.24. Suppose π_0, π_1 are two of the nine π -variants. A total relation \mathcal{R} from π_0 to π_1 is a π -subbisimulation if it is a codivergent bisimulation and the following statements are valid whenever $P\mathcal{R}Q$:

- (1) If $P \xrightarrow{\ell} P'$ then $Q \xrightarrow{\ell} Q'$ and $P'\mathcal{R}Q'$.
- (2) If $Q \xrightarrow{\ell} Q'$ then $P \xrightarrow{\ell} P'$ and $P'\mathcal{R}Q'$.

We write $\pi_0 \sqsubseteq_{\pi} \pi_1$ if there is a π -subbisimulation from π_0 to π_1 .

If $\pi_0 \sqsubseteq_{\pi} \pi_1$ then the largest π -subbisimulation from π_0 to π_1 exists, which is necessarily extensional and equipollent. Hence the following lemma.

LEMMA 4.25. *If $\pi_0 \sqsubseteq_{\pi} \pi_1$ then $\pi_0 \sqsubseteq \pi_1$.*

The converse of the lemma also holds.

THEOREM 4.26. *Suppose π_0, π_1 are two of the nine π -variants. Then $\pi_0 \sqsubseteq_{\pi} \pi_1$ if and only if $\pi_0 \sqsubseteq \pi_1$.*

PROOF. We only have to prove that $\pi_0 \sqsubseteq \pi_1$ implies $\pi_0 \sqsubseteq_{\pi} \pi_1$, which amounts to showing that \sqsubseteq is a π -subbisimulation from π_0 to π_1 . But this is just the proof of Theorem 4.23. \square

COROLLARY 4.27. *Suppose π_0, π_1 are two of the nine π -variants. If $\pi_0 \sqsubseteq \pi_1$ then there is a unique interpretation of π_0 into π_1 .*

Fu and Lu [2010] have studied the relative expressive power of the nine π -variants in terms of a relationship, called codivergent subbisimilarity in [Fu and Lu 2010], that is weaker than the π -subbisimulation of Definition 4.24. The difference is that in [Fu and Lu 2010] only the weak bisimulation property is required whereas in Definition 4.24 the branching style bisimulation is referred to. However the expressiveness results about the π -variants obtained in [Fu and Lu 2010] should remain the same had we apply the subbisimilarity of this paper as the criterion. This is because a negative result by a certain criterion remains valid if a stronger criterion is adopted and all the encodings supporting the positive results in [Fu and Lu 2010] satisfy the stronger requirement of the branching style bisimulation.

We have therefore placed the results in [Fu and Lu 2010] on a firmer foundation.

4.6 Expressiveness of Polyadic Pi

It has been a folklore that the polyadic π -calculus cannot be coded up in the monadic π -calculus. In this section we formally prove this popular belief using the subbisimilarity criterion. Let π^k , for $k \geq 1$ be the k -ary polyadic π -calculus whose prefix is given by the following grammar:

$$\pi^k := n(x_1, \dots, x_k) \mid \bar{n}\langle n_1, \dots, n_k \rangle.$$

The 1-ary polyadic π -calculus is just the monadic π -calculus. The external π^k -bisimilarity \approx_{π^k} is defined in the standard manner. The coincidence between \approx_{π^k} and $=_{\pi^k}$ can be established by recycling the proof of Theorem 3.20.

PROPOSITION 4.28. *For each $k \geq 2$ the relations $\approx_{\pi^k}, =_{\pi^k}$ coincide.*

Using Proposition 4.28 it is easy to show that π^k is a submodel of π^{k+1} and that the latter is strictly more expressive than the former.

THEOREM 4.29. $\pi \sqsubset \pi^2 \sqsubset \pi^3 \sqsubset \pi^4 \sqsubset \dots$

PROOF. We only prove $\pi^2 \not\sqsubseteq \pi^1$. Consider the π^2 -processes defined as follows:

$$\begin{aligned} C_d^2 &\stackrel{\text{def}}{=} !a(x, y).\bar{d}\langle x, y \rangle, \\ C_e^2 &\stackrel{\text{def}}{=} !a(x, y).\bar{e}\langle x, y \rangle, \\ C_\vee^2 &\stackrel{\text{def}}{=} a(x, y).([x=y]\bar{d}\langle x, y \rangle \mid [x \neq y]\bar{e}\langle x, y \rangle). \end{aligned}$$

Let D_d^2, D_e^2, D_\vee^2 be the interpretations in π of C_d^2, C_e^2, C_\vee^2 respectively, and let $\bar{A}_{f,g}, \bar{A}_f, \bar{A}_g, \bar{A}_a$ be respectively the interpretations of $\bar{a}\langle f, g \rangle, \bar{a}\langle f, f \rangle, \bar{a}\langle g, g \rangle, \bar{a}\langle a, a \rangle$. If any of $\bar{A}_{f,g}, \bar{A}_f, \bar{A}_g, \bar{A}_a$ could do a bound output action at a , a contradiction would be derived. Otherwise $\bar{A}_{f,g}$ would be able to perform an output action that is also admitted by one of $\bar{A}_f, \bar{A}_g, \bar{A}_a$, which leads to a contradiction again. \square

5. THEORY OF COMPLETENESS

The four principles introduced in Section 1 do not rule out uninteresting models. How interesting should a model of interaction be? One interpretation, and probably the only interpretation, is that a model of interaction should allow one to solve interesting problems. So the question is split into two:

- (1) what are the interesting problems? and
- (2) how do we place a minimal requirement on a model so that it does provide solutions to the interesting problems?

A preliminary answer to the second question is in terms of expressive completeness: There exists a least expressive model that admits the solutions to the interesting problems. The existence of the universal relationship \sqsubseteq makes it possible to formalize this idea. How powerful should the initial model be? Since Theory of Interaction aims at a uniform treatment of both the computation models and the interaction models, the only reasonable assumption is that the interesting problems are those that are solvable by the Turing powerful machines. Hence the preliminary answer to the first question is this: All computable functions are definable in the initial model. There are a number of well known computation models, all of them can be

extended to interaction models. These interaction models may vary in the degree of nondeterminism, the control power, the distinguishing power and so on. The differences are suppressed in the computation models due to the absence of external interactions, and are largely ignored since the focus has been on the functions definable in the models. But the differences do imply that the interactive versions of the computation models are generally incompatible. What we are seeking is a model that provides just enough computational and interactional primitives. The \mathbb{C} -calculus is an ideal candidate for the following reasons:

- (1) A functional \mathbb{C} -process prescribes what to compute, not how to compute. It does however tell if a computation terminates. From the point of view of computation the requirement is minimal.
- (2) The input and the output mechanism of the \mathbb{C} -calculus is very elementary from the point of view of interaction.
- (3) There is not any nondeterminism in any atomic \mathbb{C} -process. All nondeterminism in the \mathbb{C} -calculus comes with the concurrent composition operator.
- (4) The equality theory of the \mathbb{C} -calculus is extremely simple. The proof of Theorem 3.14 is another evidence that there is little redundancy in \mathbb{C} .

Let \mathfrak{Mod} be the class of all the models of interaction. The first fundamental postulate of Theory of Interaction states that all the models in \mathfrak{Mod} are conservative extensions over \mathbb{C} .

Axiom of Completeness. $\forall \mathbb{M} \in \mathfrak{Mod}. \mathbb{C} \sqsubseteq \mathbb{M}$.

Since Theory of Interaction is a formal theory for both the computation models and the interaction models, the Axiom of Completeness is best seen as a formalization of the Church-Turing Thesis.

It must be pointed out that the subbisimilarity referred to in the Axiom of Completeness is not required to be closed under the localization operator for the reason that the \mathbb{C} -model does not have it. The role of the localization operator is to define computations. In \mathbb{C} the computations are defined in the meta logic rather than within the model. There is really no need for the operator in \mathbb{C} .

Axiom of Completeness has significant implication to the process theory. A calculus \mathbb{L} that fails $\mathbb{C} \sqsubseteq \mathbb{L}$ is either too weak to define all the recursive functions, or is lack of an interaction mechanism that admits proper communications. As mentioned before, the purpose of introducing an interaction model is precisely to internalize the meta operations like the instantiations of function parameters, the announcements of computing results. If the interactions are useful to the participants at all, it should be possible that the correct inputs are picked up in an orderly manner without corruption, and the results are released to the targeted receivers eventually. The failure of \mathbb{L} to satisfy $\mathbb{C} \sqsubseteq \mathbb{L}$ is an obvious indication that \mathbb{L} cannot be considered as both a computation model and an interaction model. We shall use the phrase ‘ \mathbb{M} is complete’ to refer to the fact that $\mathbb{C} \sqsubseteq \mathbb{M}$.

Axiom of Completeness points out the inadequacy of some of the Turing completeness claims stated in the process calculus literature. The criticism is that the proofs of these claims boil down to showing that the target models appear Turing complete to someone *outside* the models. This level of completeness can be

exploited to establish undecidability results. It is however almost useless to programming since a piece of programme in a closed model never communicates to anyone outside the model. Our view is that the processes of an interaction model should appear Turing complete to the processes *inside* the model. In reality it is this internal completeness that truly matters.

Axiom of Completeness has far-reaching implications to practice. Suppose \mathbb{M} is a model of interaction. We would like to construct an \mathbb{M} -process *TwoColor* which after inputting a graph at channel a returns *truth* (*false*) at channel b if the graph is (not) two colorable. By the Axiom of Completeness, such an \mathbb{M} -process must exist. Let's see another example. We will show below that the π -calculus is complete. So there must be a π -process that after receiving a natural number i at channel a outputs the i -th Fibonacci number at channel b , and then it is ready to input another number at a . The Axiom of Completeness allows us to talk about a process with certain functionality without worrying about its definition.

In what follows we discuss the membership status for the prime models.

5.1 Complete Model

We prove in this section that the three models defined in Section 2 are indeed complete. A proof of completeness can be structured in four steps:

- (1) Define a map from the set \mathcal{E} of the functional \mathbb{C} -processes, the output \mathbb{C} -processes and Ω to $\mathcal{P}_{\mathbb{M}}$.
- (2) Extend \mathcal{E} to a map from $\mathcal{P}_{\mathbb{C}}$ to $\mathcal{P}_{\mathbb{M}}$ by letting $\mathcal{E}(P_0 | P_1) \stackrel{\text{def}}{=} \mathcal{E}(P_0) | \mathcal{E}(P_1)$.
- (3) Prove that the composition $\mathcal{E}; =_{\mathbb{M}}$ is equipollent, codivergent and bisimilar. Notice that $\mathcal{E}; =_{\mathbb{M}}$ is closed under composition by definition.
- (4) Argue that $\mathcal{E}; =_{\mathbb{M}}$ is sound.

Suppose $P_0 =_{\mathbb{C}} P_1$, $\mathcal{E}(P_0) =_{\mathbb{M}} Q_0$ and $\mathcal{E}(P_1) =_{\mathbb{M}} Q_1$. If $\mathcal{E}; =_{\mathbb{M}}$ is equipollent and codivergent, then Ω must be correctly encoded. It follows immediately that $\mathcal{E}(P_0) =_{\mathbb{M}} \mathcal{E}(P_1)$, thanks to Theorem 3.14. Hence $Q_0 =_{\mathbb{M}} Q_1$. So the soundness comes for free once (3) has been done. We conclude that practically only step (1) and step (3) are compulsory.

By Church-Turing Thesis every computable function can be implemented by a Turing Machine. It is obvious that a process of the form $F_a^b(f(x))$ can be coded up by an AITM. An output process of the form $\bar{a}(n)$ can also be easily translated to an ITM. By composing with the absolute equality one gets a subbisimilarity from \mathbb{C} to \mathbb{IM} .

PROPOSITION 5.1. $\mathbb{C} \sqsubseteq \mathbb{IM}$.

A straightforward corollary of Proposition 5.1 is that \mathbb{INM} is also complete.

In [Fu 2011b] an encoding of the recursive functions [Rogers 1987] into \mathbb{VPC} is given. By composing with $=_{\mathbb{VPC}}$ the encoding gives rise to a subbisimilarity from \mathbb{C} to \mathbb{VPC} , which immediately implies the completeness of the latter.

THEOREM 5.2. $\mathbb{C} \sqsubseteq \mathbb{VPC}$.

The construction does not make use of any choice operator. Hence the corollary.

COROLLARY 5.3. $\mathbb{C} \sqsubseteq \mathbb{VPC}^-$.

\mathbb{VPC}^- is the minimal model among the class of the value-passing calculi discussed in [Fu 2011b]. Using the terminology of this paper, \mathbb{VPC}^- is subbisimilar to every value-passing calculus. It follows that all the value-passing calculi are complete. Using the result from [Fu 2011b], we may summarize as follows: A value-passing calculus is complete if and only if it has a numeric system.

Next we prove that π^M is complete. We will show that the recursive functions are definable in π^M , which is more than necessary for our purpose.

The encoding of the recursive functions into the π -calculus makes use of the processes defined in Section 4.2. The structural definition on the nonfunctional processes is as follows:

$$\begin{aligned} \llbracket \mathbf{0} \rrbracket^\pi &\stackrel{\text{def}}{=} \mathbf{0}, \\ \llbracket \Omega \rrbracket^\pi &\stackrel{\text{def}}{=} (c)(\bar{c}c \mid !c(x).\bar{x}x), \\ \llbracket \bar{b}(n) \rrbracket^\pi &\stackrel{\text{def}}{=} \llbracket n \rrbracket_b^\pi, \\ \llbracket P \mid Q \rrbracket^\pi &\stackrel{\text{def}}{=} \llbracket P \rrbracket^\pi \mid \llbracket Q \rrbracket^\pi, \end{aligned}$$

The translations of the successor function, constant functions, projection functions and composition functions are given below. In the following structural definition we write $F_{a_1, \dots, a_n}^b(\mathbf{f}(x_1, \dots, x_n))$ to force the interpretation of the n -ary recursive function $\mathbf{f}(x_1, \dots, x_n)$ to be of the right type. The process $\llbracket F_{a_1, \dots, a_n}^b(\mathbf{f}(x_1, \dots, x_n)) \rrbracket^\pi$ must pick up the inputs consecutively at a_1, \dots, a_n and deliver the result at b .

$$\begin{aligned} \llbracket F_{a_1}^b(\mathbf{s}(x)) \rrbracket^\pi &\stackrel{\text{def}}{=} (d_1)Rep(a_1, d_1).(c)Copy(d_1, c).\bar{b}(e, f).\bar{c}c, \\ \llbracket F_{a_1, \dots, a_n}^b(\underline{n}(x_1, \dots, x_n)) \rrbracket^\pi &\stackrel{\text{def}}{=} (d_1)Rep(a_1, d_1) \cdots (d_n)Rep(a_n, d_n).\llbracket n \rrbracket_b^\pi, \\ \llbracket F_{a_1, \dots, a_n}^b(\mathbf{p}_n^i(x_1, \dots, x_n)) \rrbracket^\pi &\stackrel{\text{def}}{=} (d_1)Rep(a_1, d_1) \cdots (d_n)Rep(a_n, d_n).Copy(d_i, b), \\ \llbracket F_{a_1, \dots, a_n}^b(\mathbf{f}(\mathbf{f}_1(\tilde{x}), \dots, \mathbf{f}_i(\tilde{x}))) \rrbracket^\pi &\stackrel{\text{def}}{=} (d_1)Rep(a_1, d_1) \cdots (d_n)Rep(a_n, d_n).(c_1 \dots c_i) \\ &\quad (\llbracket F_{d_1, \dots, d_n}^{c_1}(\mathbf{f}_1(\tilde{x})) \rrbracket^\pi \mid \dots \mid \llbracket F_{d_1, \dots, d_n}^{c_i}(\mathbf{f}_i(\tilde{x})) \rrbracket^\pi \\ &\quad \mid \llbracket F_{c_1, \dots, c_i}^b(\mathbf{f}(\tilde{x})) \rrbracket^\pi). \end{aligned}$$

The encodings of the recursion functions and the minimization functions are slightly more involved.

(1) $\llbracket F_{a_1, \dots, a_{n+1}}^b(\mathbf{rec} z.[\mathbf{f}(\tilde{x}, x', z), \mathbf{g}(\tilde{x})]) \rrbracket^\pi$ is the following process

$$(d_1)Rep(a_1, d_1) \cdots (d_{n+1})Rep(a_{n+1}, d_{n+1}).(f)(\bar{f}(b, d_{n+1}) \mid Rec),$$

where Rec stands for the π -process

$$\begin{aligned} &!\mathbf{f}(v, x).x(y, z).(z.\llbracket F_{d_1, \dots, d_n}^v(\mathbf{g}(x_1, \dots, x_n)) \rrbracket^\pi \\ &\mid y(x).(d)\bar{f}(d, x).\llbracket F_{d_1, \dots, d_n}^v dx(\mathbf{f}(x_1, \dots, x_{n+1}, z)) \rrbracket^\pi). \end{aligned}$$

(2) $\llbracket F_{a_1, \dots, a_n}^b(\mu z.\mathbf{f}(\tilde{x}, z)) \rrbracket^\pi$ is the following process

$$(d_1)Rep(a_1, d_1) \cdots (d_n)Rep(a_n, d_n).(e)(\llbracket F_{d_1, \dots, d_n, d}^e(\mathbf{f}(\tilde{x}, z)) \rrbracket^\pi \mid \llbracket !\Omega \rrbracket_d^\pi \mid Mu)$$

where Mu stands for

$$\begin{aligned} &\bar{f}(e, d) \mid !\mathbf{f}(x, w).x(y, z).(z.Copy(w, b) \\ &\mid y.(d)(\bar{d}(c, g).\bar{c}w \mid (e)(\llbracket F_{d_1, \dots, d_n}^e(\mathbf{f}(\tilde{x}, z)) \rrbracket^\pi \mid \bar{f}(e, d)))). \end{aligned}$$

By associating a particular recursive function to every computable function, the above encoding generates the relation $\mathcal{T}_\pi \stackrel{\text{def}}{=} \{(P, \llbracket P \rrbracket^\pi) \mid P \in \mathcal{P}_\mathbb{C}\}$. It should be clear that \mathcal{T}_π is equipollent and closed under composition. It is not a bisimulation, the reason being that a computational descendant of $\llbracket P \rrbracket^\pi$ is not in the relation. But the composition $\mathcal{T}_\pi; =_\pi$ does not have that problem.

THEOREM 5.4. $\mathbb{C} \sqsubseteq \pi^M$.

5.2 Incompleteness Result

It turns out that some well-known process calculi fail the Axiom of Completeness. We show in this section that CCS and the higher order process calculus are incomplete, the reason being that CCS has a very weak interaction mechanism and the higher order process calculus has an insufficient control power.

5.2.1 *CCS*. Milner's *Calculus of Communicating System* [Milner 1980; 1989a], CCS for short, provides a prototype for models of interaction. The interaction primitive of CCS is simplified to bare minimal. All interactions in CCS are synchronization. Nothing is communicated in any interaction. There are a number of variants of CCS, most of which have been mentioned in [Milner 1989a]. A detailed discussion of the relative expressiveness of CCS is given by Fu and Lu [2010]. The variant we shall be concerned with has the guarded choice. The unguarded choice is disowned by the Theory of Interaction. The set \mathcal{P}_{CCS} is constructed from the following grammar:

$$P := \sum_{i \in I} \ell_i.P_i \mid D(a_1, \dots, a_n)$$

where I is a finite indexing set and ℓ_i ranges over the set $\mathcal{N} \cup \overline{\mathcal{N}}$ for every $i \in I$, $\sum_{i \in I} \ell_i.P_i$ is a guarded choice, and $D(a_1, \dots, a_n)$ is the instantiation of a parametric definition at the names a_1, \dots, a_n . Using the action set $\mathcal{A}_{\text{CCS}} = \mathcal{N} \cup \overline{\mathcal{N}} \cup \{\tau\}$, the semantics of CCS is defined by the following rules.

Choice

$$\frac{}{\sum_{i \in I} \ell_i.P_i \xrightarrow{\ell_i} P_i} \quad i \in I$$

Interaction

$$\frac{P \xrightarrow{\ell} P' \quad Q \xrightarrow{\bar{\ell}} Q'}{P \mid Q \xrightarrow{\tau} P' \mid Q'}$$

Recursion

$$\frac{T\{\tilde{c}/\tilde{x}\} \xrightarrow{\lambda} P'}{D(\tilde{c}) \xrightarrow{\lambda} P'} \quad D(\tilde{x}) = T.$$

Despite of the result proved in [Busi et al. 2003] that CCS is Turing complete, the intuition is however that CCS apparently lacks of the ability to pick up a value or to deliver a result in a proper manner. This intuition is confirmed below.

THEOREM 5.5. *CCS is not complete.*

- (5) Suppose the number of the observable F'_{2i} 's is finite. Then there must be some $k > 1$ such that $B'_{2k}, B'_{2k+2}, B'_{2k+4}, \dots$ are all observable. Each process in the sequence contains one and only one subterm in summation form that may induce external actions for the process. It follows that there is an infinite subsequence $B'_{2k_1}, B'_{2k_2}, B'_{2k_3}, \dots$ such that all the external actions are induced by the subterms that are syntactically identical, the reason being that all these subterms are derivatives of either B or F . Due to dynamic binding it is possible that there are B'_{2k_i}, B'_{2k_j} such that the set of the external actions admitted by B'_{2k_i} is different from that of B'_{2k_j} . But clearly there must be an infinite subsequence $B'_{2k'_1}, B'_{2k'_2}, B'_{2k'_3}, \dots$ in which all processes may perform the same set of external actions. Now the crucial point is that there must be two processes $B'_{2k'_i}, B'_{2k'_j}$, where $1 \leq k'_i < k'_j$, that enjoy the following property:

- (†) For each action ℓ , $B'_{2k'_i}$ becomes observable after performing ℓ if and only if $B'_{2k'_j}$ becomes observable after performing ℓ .

Let $f(x)$ be the following computable function

$$\text{if } x < 2k'_j \text{ then } \underline{0} \text{ else diverge,}$$

and let D be a CCS process satisfying $F_b^c(f(x)) \mathfrak{F} D \dashv$. Clearly D' is observable whenever $B_{2k'_i} | D \xrightarrow{\ell} D'$. By property (†) we must have that $B_{2k'_j} | D \xrightarrow{\ell} D''$ for some observable D'' . But this contradicts to the fact that all the change-of-state actions of $B_{2k'_j} | D$ should lead to unobservable states.

- (6) If there are infinite observable F'_{2i} 's, then we can apply the argument in (5) to derive a similar contradiction. So this case is also impossible.

We conclude that $\mathbb{C} \not\subseteq \text{CCS}$. \square

The above proof refers neither to the choice operator nor to the finite branching property. Therefore it is also valid for the CCS with binary unguarded choice operator and parametric definition. This is the most expressive CCS variant studied in [Fu and Lu 2010]. So we have justified the general statement of Theorem 5.5.

5.2.2 Process-Passing Calculus. The process-passing calculus, called Λ -calculus in this paper, extends the lazy λ -calculus with the ability to interact externally. The set of the Λ -terms \mathcal{T}_Λ is generated by the following grammar:

$$T := X \mid a(X).T \mid \bar{a}(T).T.$$

The term variable X is bound in $a(X).T$. The set \mathcal{P}_Λ of the Λ -processes consists of those Λ -terms in which all the term variables are bound. The label set \mathcal{L}_Λ is

$$\{a(L), (\tilde{c})\bar{a}(L) \mid L \in \mathcal{P}_\Lambda \wedge \tilde{c}, a \in \mathcal{N} \wedge a \notin \{\tilde{c}\} \wedge \{\tilde{c}\} \subseteq \text{gn}(L)\}.$$

In both $a(L)$ and $(\tilde{c})\bar{a}(L)$, the interface name is a . The rules defining the operational semantics are given below.

Action

$$\frac{}{a(X).T \xrightarrow{a(L)} T\{L/X\}} \quad \frac{}{\bar{a}(L).T \xrightarrow{\bar{a}(L)} T}$$

Interaction

$$\frac{S \xrightarrow{a(L)} T' \quad T \xrightarrow{(\tilde{c})\bar{a}(L)} T'}{S | T \xrightarrow{\tau} (\tilde{c})(S' | T')}$$

Localization

$$\frac{T \xrightarrow{(\tilde{c})\bar{a}(L)} T'}{(d)T \xrightarrow{(d)(\tilde{c})\bar{a}(L)} T'} \quad d \in \text{gn}(L) \setminus \{\tilde{c}\}.$$

In our semantics we require that a term released in an output action must be a process. The operational semantics of the Λ -calculus is complicated by the fact that the transportation of a process might extend the scope of a localization operator.

It is well-known that the Λ -calculus is at most as expressive as the π -calculus. This fact is formally established by Sangiorgi in [Sangiorgi 1992; 1993]. Prior to Sangiorgi's work, Thomsen has discussed the relationship between CHOCS, the calculus of higher order communicating systems, and the π -calculus. A related work is described in [Amadio 1993]. It is worthwhile recalling the encoding.

PROPOSITION 5.6. $\Lambda \sqsubseteq \pi$.

PROOF. The Sangiorgi-Thomsen's translation of the Λ -calculus in the π -calculus is based on an injective function $st : \mathcal{V}_p \rightarrow \mathcal{V}_n$. We assume that $st(X) = x$ and so on. The extensional translation is defined as follows:

$$\begin{aligned} \llbracket X \rrbracket_{st} &\stackrel{\text{def}}{=} x, \\ \llbracket a(X).T \rrbracket_{st} &\stackrel{\text{def}}{=} a(x).\llbracket T \rrbracket_{st}, \\ \llbracket \bar{a}(T).T' \rrbracket_{st} &\stackrel{\text{def}}{=} (c)(\bar{a}c.\llbracket T' \rrbracket_{st} | !\bar{c}.\llbracket T \rrbracket_{st}). \end{aligned}$$

The encoding generates a sound, equipollent, extensional, codivergent bisimulation by composing with $=_\pi$. \square

An interesting open problem is if the Λ -calculus is as expressive as the π -calculus. Our intuition tells us that the answer is negative. In the π -calculus a received name can be used in a prefix, whereas in the Λ -calculus a received process cannot act as a prefix of anything. In other words, the Λ -calculus has far less control power than the π -calculus. This intuition is justified by the next theorem.

THEOREM 5.7. *The Λ -calculus is not complete.*

PROOF. The proof is similar to the proof of Theorem 5.5. Assume there were a subbisimilarity \mathfrak{F} from the \mathbb{C} -calculus to the Λ -calculus. We derive a contradiction in a few steps.

- (1) Let B_i, B be such that $\bar{b}(i) \mathfrak{F} B_i \not\leftrightarrow$ and $F_b^c(s(x)) \mathfrak{F} B \not\leftrightarrow$. Assume that $B_i | B \xrightarrow{\tau} C_1$ is caused by an interaction between B_i and B at a global name d . If $B_i | B = C_1$ then $C_1 \rightarrow^* C_2$ for some C_2 such that C_2 does not admit any computation. It is easy to see that C_2 must be able to perform both an input action at d and an output action at d . These two complementary actions contribute to an internal action. Continuing in this way one could construct an infinite sequence of tau actions. This renders a contradiction since

- $\bar{b}(\underline{i}) \mid F_b^c(s(x))$ does not admit any infinite tau action sequence. We conclude that every immediate tau action of $B_i \mid B$ is a change-of-state internal action.
- (2) Let B^\dagger be such that $F_b^c(\uparrow) \mathfrak{F} B^\dagger \dashrightarrow$. As is done in (1) one can prove that the immediate tau action of $B_i \mid B^\dagger$ must be a change-of-state action. Consequently C_0 must be unobservable whenever $B_i \mid B^\dagger \xrightarrow{\tau} C_0$.
- (3) Since there is no choice operator in the Λ -calculus, it follows from (2) that only one prefix term in B_i is fireable. Similarly only one prefix term in B^\dagger may act.
- (4) Now let G_i, G^\dagger be such that $\bar{g}(\underline{i}) \mathfrak{F} G_i$ and $F_g^h(\uparrow) \mathfrak{F} G^\dagger$. The global name at which the processes G_i, G^\dagger interact must be different from the global name at which the processes B_i, B^\dagger interact. Otherwise $B_i \mid G^\dagger$ would be able to perform a change-of-state action, rendering a contradiction. The consequence is that we can always choose a name say d such that whenever $\bar{d}(\underline{i}) \mathfrak{F} D$ then the only external action of D is carried out at a name that is not in any specific finite name set.
- (5) Suppose $B_i \xrightarrow{b(A'')} S_i\{A''/X\}$ and $B \xrightarrow{\bar{d}(\underline{i})} A'$. It should be clear that

$$B_i \mid B \xrightarrow{\tau} (\bar{d})(S_i\{A''/X\} \mid A') \quad (19)$$

is bisimulated by $\bar{b}(\underline{i}) \mid F_b^c(s(x)) \xrightarrow{\tau} \bar{c}(\underline{i}+1)$. Now let S'_i be such that $S_i \Longrightarrow S'_i$ and that S'_i cannot perform any tau action. Clearly $(\bar{d})(S_i\{A''/X\} \mid A') \rightarrow^* (\bar{d})(S'_i\{A''/X\} \mid A')$. By structural induction it is easy to prove that

$$S'_i\{A''/X\} = S''_i\{A''/X\} \mid \prod_{n_i} A''$$

for some $n_i \geq 0$ and some S''_i in which X is guarded. We can rewrite (19) to

$$B_i \mid B \xrightarrow{\tau} (\bar{d})(S''_i\{A''/X\} \mid \prod_{n_i} A'' \mid A').$$

For a number j that differs from i , we also have

$$B_j \mid B \xrightarrow{\tau} (\bar{d})(S''_j\{A''/X\} \mid \prod_{n_j} A'' \mid A')$$

for some n_j and some S''_j in which X is guarded. The external actions of

$$(\bar{d})(S''_i\{A''/X\} \mid \prod_{n_i} A'' \mid A') \text{ and } (\bar{d})(S''_j\{A''/X\} \mid \prod_{n_j} A'' \mid A')$$

must be caused by the components $\prod_{n_i} A'' \mid A'$ and $\prod_{n_j} A'' \mid A'$ respectively. Without loss of generality we assume $n_i < n_j$. Consider the process F satisfying $F_c^f(\underline{f}_{i+1 \rightarrow i+1}(x)) \mathfrak{F} F \dashrightarrow$. We have the following

$$(\bar{d})(S''_i\{A''/X\} \mid \prod_{n_i} A'' \mid A') \mid F \rightarrow^* \xrightarrow{\tau} F' \mathfrak{F}^{-1} \bar{f}(\underline{i}+1).$$

According to (4) we can choose f in such a way that the next external action of F' is caused by a descendant of F . But then we must have

$$(\bar{d})(S''_j\{A''/X\} \mid \prod_{n_j} A'' \mid A') \mid F \rightarrow^* \xrightarrow{\tau} \Downarrow,$$

contradicting to the definition of $f(x)$. So this case is impossible.

(6) Suppose $B_i \xrightarrow{(\tilde{d}_i)\bar{b}(A_i)} B'_i$ and $B \xrightarrow{b(A_i)} T\{A_i/X\}$. It should be clear that

$$B_i | B \xrightarrow{\iota} (\tilde{d}_i)(B'_i | T\{A_i/X\}) \quad (20)$$

is bisimulated by $\bar{b}(0) | F_b^c(\mathfrak{s}(x)) \xrightarrow{\iota} \bar{c}(1)$. According to (4) we may choose the name c in such a way that the immediate external action of $(\tilde{d}_i)(B'_i | T\{A_i/X\})$ is carried out at a name different from any name appeared in B_i . Consequently the next external action of $(\tilde{d}_i)(B'_i | T\{A_i/X\})$ must be caused by T . It follows from (20) that

$$B_{i+1} | B | F \xrightarrow{\iota} (\widetilde{d_{i+1}})(B'_{i+1} | T\{A_{i+1}/X\}) | F \xrightarrow{*} \xrightarrow{\iota} F'' \Downarrow$$

for some F'' , where F is the process introduced in (5). By (5) the change-of-state action of $(\widetilde{d_{i+1}})(B'_{i+1} | T\{A_{i+1}/X\}) | F$ is caused by F performing an input action. By assumption the external action of F'' is caused by a descendant of F . It is easy to see from these facts that

$$B_{i+2} | B | F \xrightarrow{\iota} (\widetilde{d_{i+2}})(B'_{i+2} | T\{A_{i+2}/X\}) | F \xrightarrow{*} \xrightarrow{\iota} \Downarrow,$$

contradicting to the definition of $f_{i+1 \rightarrow i+1}(x)$.

In summary, $\mathbb{C} \not\sqsubseteq \Lambda$. \square

It is shown in [Lanese et al. 2010] that the abstraction-passing calculi [Sangiorgi 1992] are strictly more expressive than the process-passing calculi. It remains to see if any of these stronger higher order process calculi is complete.

6. RELATED WORK

The development of the process theory can be summarized in a number of ways. A handy approach is to classify the stages of the development by the influential models that have been studied in the process theory. Our understandings of the theories of equality, expressiveness, and completeness have been progressing significantly with the investigation of each of these models.

The influence of CCSP model, a shorthand for Milner's CCS [Milner 1980; 1989a] and Hoare's CSP [Hoare 1978; 1985], reaches to almost every corner of the theory. Apart from the introduction of the fundamental operators of the process theory ($\mathbf{0}$, concurrent operator, localization operator), the studies of CCSP have led to a theory of process equality [Milner 1981; 1984; 1989b; Hennessy and Milner 1985; Roscoe 1997] that has been successfully applied/extended to other process models. The results established in the equality theory have been exploited in Bergstra and Klop's ACP [Baeten and Weijland 1990] that features an axiomatic approach. There are a number of decidability results for the variants of CCS/ACP [Jančar and Moller 1999; Burkart et al. 2001; Srba 2004; Kučera and Jančar 2006], some of which can be used to establish separation results. However the proper investigations in the relative expressiveness of the variants of CCS have been a recent endeavor [Busi et al. 2003; Giambiagi et al. 2004; Busi et al. 2004; Busi and Zavattaro 2004; Palamidessi 2003; Fu and Lu 2010]. The characterization by [Fu and Lu 2010] of the expressiveness of nine CCS variants remains valid if the subbisimilarity relationship of this paper is adopted as the expressiveness criterion.

In reality the processes communicate messages from one to another. The value-passing calculi, in which the messages are coded up by the natural numbers, were introduced in the CCSP framework [Milner 1989a; Hoare 1985]. A systematic studies of the value-passing mechanism have been carried out by Hennessy and his collaborators [Hennessy 1991; Hennessy and Ingólfssdóttir 1993a; 1993b; Hennessy and Lin 1995; 1996; Rathke 1997; Hennessy and Lin 1997; Hennessy et al. 1997]. It was discovered in these studies that the symbolic approach [Hennessy and Lin 1995; Ingólfssdóttir and Lin 2001] plays an important role in analyzing the branching structures of the value-passing calculi. In all these studies, the value domains are treated as oracles. This isolation of concern facilitates the development of the equality theory. It is however not at all helpful to the expressiveness study. A self-contained treatment of the theory of the value-passing calculi is carried out in the satellite paper by the present author [Fu 2011b].

The search for *the* λ -calculus of the concurrent computations has resulted in an important discovery of the process theory, the π -calculus of Milner, Parrow and Walker [Milner et al. 1992; Parrow 2001; Sangiorgi and Walker 2001b]. The most noteworthy feature of the π -calculus is the simple and natural construction of the conditional processes in terms of the match and mismatch operators. The studies in the name-passing paradigm [Parrow and Sangiorgi 1995; Boreale and De Nicola 1995; Lin 1995a; 1995b; Sangiorgi 1996c; Lin 1996; 1998; 2003; Fu and Yang 2003; Fu 2005] clarify the indispensable role of the localization operator and its tricky presence in the original formulation of the π -calculus. The investigations into the variants of the π -calculus [Honda and Tokoro 1991a; 1991b; Boudol 1992; Amadio et al. 1998; Sangiorgi 1996b; Boreale 1996; Fu 1997; Parrow and Victor 1997; 1998; Fu 1999; Merro 2000; Merro and Sangiorgi 2004; Fu 2003] brings out the agility of the name-passing mechanism. The proposal of the barbed bisimilarity by Milner and Sangiorgi [1992] for the name-passing calculi is a major step in the study of the theory of equality. The research in the π -calculus has also advanced the theory of expressiveness. Milner's encoding of the lazy λ -calculus [Milner 1992] has inspired several follow-up works that relate the operational and the observational semantics of the computation model to those of the process models [Sangiorgi 1994; 1995; Fu 1999; Merro 2000; Merro and Sangiorgi 2004; Cai and Fu 2011]. Sangiorgi's translation of the higher order process calculi [Sangiorgi 1993; 1996b; 1996a; 2001] into the π -calculus point out the subservient role of the former from the point of view of model theory. The object oriented style of the π -programming, a notable feature of the works of Milner and Sangiorgi, is emphasized by Walker's interpretation of the object oriented languages [Walker 1991; 1995]. All encodings into the π -calculus have to address the problem of full abstraction. The most recent work that attacks this issue is Cai and Fu's fully abstract encoding of the full λ -calculus [Cai and Fu 2011]. The theory of expressiveness has been significantly enriched by the works on the relative expressiveness of the various variants of the π -calculus [Honda and Tokoro 1991a; 1991b; Amadio et al. 1998; Nestmann and Pierce 1996; Merro 2000; Nestmann 2000; Palamidessi 2003; Merro and Sangiorgi 2004; Cacciagrano et al. 2006; Palamidessi et al. 2006; Cacciagrano et al. 2008] and the works [Gorla 2008b; 2008a; 2009a; 2009b; Fu 2007] that compare the π -calculus to other process models, in particularly the variants [Levi and Sangiorgi 2000; Guan et al. 2001; Phillips and

Vigliotti 2002; M. Bugliesi and Crafa 2004; Merro and Zappa Nardelli 2005; Merro and Hennessy 2006; Fu 2007] of the Ambient Calculus [Cardelli and Gordon 2000]. In retrospect one cannot help remarking that the equality theory of the π -calculus has been unnecessarily complicated, and the research on the expressiveness theory of the name-passing calculi has been slowed down, by the confusion of the name variables with the names. An elaboration on the problems caused by the confusion can be found in [Fu and Zhu 2011].

The power of the barbed bisimilarity is duly exhibited in Sangiorgi's study of the higher order calculi [Sangiorgi 1992; 1996a]. There could be several variations when defining a bisimulation equivalence for the process-passing calculi [Thomsen 1989; 1990; Sangiorgi 1992; Thomsen 1993; 1995], but it is the barbed bisimilarity that tells us which one should be preferred. It does not take much long for one to get the feeling that the process-passing mechanism has too weak a control power over the interactions to carry out the fundamental constructions possible in the π -calculus. Sangiorgi's encoding of the lazy λ -calculus in the higher order π -calculus [Sangiorgi 1993] for example has to resort to the constant definitions parametric on either names or processes. These parametric definitions are not only used locally, they are also passed from one process to another, which necessarily means that typing information has to be provided since different definitions have different numbers of parameter. Both the work of Thomsen on the higher order CCS and Sangiorgi on the higher order π -calculus suggest that the process-passing mechanism is best used along with the name-passing mechanism, which again raises the issue of type system. Having to introduce a type discipline is one way to say that the higher order mechanism belongs to programming theory but not to model theory.

6.1 On Equality

The bisimulation and the codivergence are *intensional* conditions. Intensional conditions are concerned with computations. On the other hand, the extensionality and the equipollence are *extensional* conditions. Extensional conditions are to do with interactions. If we completely ignore the intensional conditions, we may come up with the following definition.

Definition 6.1. The *extensional equality* $=_e^{\mathbb{M}}$ on \mathbb{M} is the largest equivalent, extensional and equipollent relation on $\mathcal{P}_{\mathbb{M}}$.

Definition 6.1 is the model independent formulation of the trace equivalence. See [Fu and Zhu 2011] for more on this topic. The so-called observational equivalences are obtained by strengthening Definition 6.1 with additional intensional requirements. The strong equality and the weak equality are two examples. So is the testing equivalence [Fu and Zhu 2011]. The advantage of this way of thinking about the observational equivalences is that it only produces model independent definitions. It is beyond the scope of this paper to discuss which of the equivalence relations proposed in literature [van Glabbeek 1993b; 2001] have model independent characterizations. What we do in this subsection is to comment on the major conceptual and technical contributions that relate to the present work.

6.1.1 Bisimulation. In algebraic theory bisimulation is a technique to construct the largest fixpoints. The concept was introduced to concurrency theory by Milner

[1989a] and Park [1981]. For a long time bisimulation was mainly perceived as a requirement about external actions. Many variations were proposed and studied [van Glabbeek 2001; 1993b]. It is the barbed bisimulation of Milner and Sangiorgi [1992] that brings out the power of the bisimulation of internal actions. This is a first step towards a model independent theory of process. The barbed approach, and the reductional semantics, have become a standard tool in process theory [Sangiorgi and Walker 2001b]. It is emphasized by Fu and Lu [2010] that the notion of bisimulation is implicit in Church-Turing Thesis [van Emde Boas 1990]. To prove a Turing completeness result amounts to establishing an *effective* bisimulation [Fu and Lu 2010] of computation from a known computation model to the target model. Now the key point is that a bisimulation of internal action is not the same as a bisimulation of computation. A computation is a local manipulation that does not change the ability to interact, whereas an internal action that is induced by an interaction at a global name does often change the interactability. The correct definition of the bisimulation of internal action is the essence of the branching bisimulation introduced by van Glabbeek and Weijland [1989]. The particular formulation given in Definition 3.2 is due to Baeten [Baeten 1996], which has the edge over the original formulation of van Glabbeek and Weijland [1989] in that the composition of two branching bisimulations is still a branching bisimulation. The advantage of the branching bisimulation over the weak bisimulation has been demonstrated in a series of papers by van Glabbeek and his collaborators [van Glabbeek and Weijland 1989; van Glabbeek 1993a; 1993b; 1994; van Glabbeek et al. 2009]. The branching bisimulation also appears as a more stable property than the weak bisimulation. This is manifested in a number of works.

- (1) De Nicola et al. [1990] have argued that the branching bisimilarity is the least fixpoints of the operators that admit both forward bisimulation as well as some kind of backward bisimulation.
- (2) De Nicola and Vaandrager [1995] have shown that there is a nice logical characterization of the branching bisimilarity using an additional until operator,
- (3) Baier and Hermanns [1997] have pointed out that for the fully probabilistic systems branching bisimulation is the only choice.

The importance of the branching bisimulation is best appreciated when computations are considered as first class citizens.

One of the implications of combining the barbed approach and the branching approach is that we really should only talk about the bisimulations of the internal actions. Bisimulations of the external actions are derived properties.

6.1.2 Codivergence. For self evolving objects, nontermination is the norm rather than the exception. The theory of process calculus has been criticized for not paying enough attention to divergence. It was ignored completely in the trace equivalence of CSP [Hoare 1978; 1985] and the bisimulation equivalence of CCS [Milner 1989a]. In the denotational treatment the process that can only diverge is understood as the bottom element of the domain [Amadio and Curien 1998] of the processes. The denotational approach identifies divergence to zero information or undefinedness. If the information order is mingled with the observational theories, different order relations on the processes are produced. In the testing scenario of De Nicola and

Hennessy [De Nicola and Hennessy 1984; Phillips 1987; Hennessy 1988], the must equivalence regards divergence as catastrophic. This is rectified in later modifications of the testing equivalence [Brinksma et al. 1995; Natarajan and Cleaveland 1995; Boreale et al. 1999; 2001]. In the bisimulation semantics [Walker 1990; Aceto and Hennessy 1992], divergence is respected but not bisimulated. In process algebra [Baeten and Weijland 1990], divergence is an operator defined (in)equationally. The denotational approach features a preordained predicate, often denoted by \uparrow , that is defined on the syntax of the processes, and an inactive process, denoted by \perp or Ω or Δ by various authors and called *explicit divergence*, that induces a satisfaction relationship to the predicate.

Divergence is neither a syntactical concept nor an observational concept. Its treatment should be intensional rather than extensional. The implicit definition in terms of the infinite internal action sequences should be preferred. An equality is divergence sensitive if it respects divergence. The simplest formulation of divergence sensitivity is the so-called termination preserving property. In [van Glabbeek 1993b] van Glabbeek summarizes several ways to strengthen the termination preserving property. The operational approach to divergence had been left without scrutiny for some time. It is Lohrey, D’Argenio and Hermanns who give in [Lohrey et al. 2002; 2005] for the first time an algebraic characterization of the divergence sensitive equivalences classified by van Glabbeek. Termination preservation is obviously a correct criterion if it is stated for the (deterministic) computations. It is a dubious one when stated for the internal action sequences (or nondeterministic computations). The right property that goes nicely with the bisimulation property is the codivergence heavily used by Fu and Lu [2010]. Independently van Glabbeek, Luttk and Trčka have studied in a recent paper [van Glabbeek et al. 2009] the codivergence property of the branching bisimulations. Codivergence appears in [van Glabbeek et al. 2009] as the weakest condition among several alternative formulations of the same idea. But Bisimulation Lemma clearly implies that it is as effective as the strongest formulation one may think of. As far as we know the codivergence property was stated for the first time by Priese [Priese 1978], who called it *eventually progressing property*. The equational axioms for codivergence is studied in [Fu 2011a], which is inspired by the work of Lohrey et al. [2005].

6.1.3 Extensionality. The observational theory of process is complicated by our perception that there are an almost unbounded number of choices of the observers. If the observers are external, meaning that they stay outside the model of the observees, then they may vary considerably in strength. But if the observing power of the external observers, chosen for whatever reasons, are too strong or too weak compared to the power of the observees, isn’t that suggesting that a wrong model has been chosen? We might as well start with a stronger or weaker model. If a process calculus defines a closed model of processes, which is generally accepted, then the observers ought to be internal ones. The proper assumption is that all processes of a model are observers, which leads to the environment closure property of the barbed equivalence [Milner and Sangiorgi 1992]. If one generalizes this closure property from a relation on one model to a relation from one model to another, one gets the extensionality criterion. The simple step from the environmental closure condition to the extensionality condition is what makes possible the unification of

the equality and the expressiveness relationship. The tradeoff is that generally one has to settle for *a* subbisimilarity rather than *the* subbisimilarity.

It has been suggested that a process $P | Q$ in composition form could be interpreted as $C[[P], [Q]]$ for some nontrivial context $C[-, -]$ in the target model. From the perspective of expressiveness, such a liberal ‘interpretation’ can only be understood as saying that $[[P], [Q]]$ are wrongly interpreted. In $C[[P], [Q]]$ neither $[[P]]$ nor $[[Q]]$ is a free individual soul as P, Q are.

6.1.4 Equipollence. Extensionality alone is insufficient to recover an observational equivalence. A counter example is the extensional closure of $\{(!a | !\bar{a}, !b | !\bar{b})\}$. To capture the full power of observation, one needs to talk about interactability. This is what Milner and Sangiorgi’s barbed approach has offered. In the original paper of Milner and Sangiorgi [1992], barbedness means observability. The idea was embraced in a lot of later studies and has clarified the relative roles of some of the equivalences [Sangiorgi and Walker 2001a]. In most of these studies one defines a barb as for example a subject name of an action or an external action, and then define the barbed equivalence accordingly. These variations on the barbed equivalence are not as model independent as Milner and Sangiorgi’s original definition. When generalizing relations on one model to relations between two models, it is the observability, not any definition of the barbs, that survives.

The barbed approach has promoted a shift from the labeled semantics to the reductional semantics [Berry and Boudol 1992; Milner 1992; Honda and Yoshida 1995]. While we acknowledge the importance of the reductional approach, we have to point out that it is rather easy to design a reductional semantics that cannot be justified from the perspective of interaction.

6.2 On Expressiveness

In [Nestmann 2000; Palamidessi 2003; Parrow 2006] the authors discuss several expressiveness criteria proposed in literature. In this subsection we examine these criteria in the light of the Theory of Interaction. Suppose that there are two translations:

$$\mathbb{M}_0 \xrightarrow{\mathcal{T}} \mathbb{M}_1 \xrightarrow{\mathcal{T}'} \mathbb{M}_2,$$

where \mathcal{T} asserts that \mathbb{M}_1 is at least as expressive as \mathbb{M}_0 and \mathcal{T}' asserts that \mathbb{M}_2 is at least as expressive as \mathbb{M}_1 . Whatever the criteria are taken for the assertions, it *must* follow that \mathbb{M}_2 is at least as expressive as \mathbb{M}_0 . In sequel we will reject any criterion that does not enjoy transitivity.

Every criterion for expressiveness should refer to some equivalence relation. For simplicity we shall only use the weak equality, and accordingly weak bisimulations, in the following discussions.

6.2.1 Leader Election Problem. If there is a problem that can be solved in \mathbb{L} but is unsolvable in \mathbb{L}' , then the problem separates \mathbb{L} from \mathbb{L}' since the latter cannot be more expressive than the former. The Leader Election of distributed systems [Garcia-Molina 1982; Stoller 2000] is one such problem that is often used to tell apart process calculi [Bougé 1988; Palamidessi 2003; Phillips and Vigliotti 2006; Vigliotti et al. 2007; Phillips and Vigliotti 2008]. In the theory of distributed computing an important issue is about reaching a consensus. The problem looks

for a method to reach an agreement, say a number less than n , among a set of n processes. It has been proved that such a method does not exist for the general consensus problem if processes may fail. The problem does have a solution if we assume that no participating processes can ever fail or that there is a timeout mechanism available. In the restricted scenario, a simple leader election algorithm suffices. In process theory failure is interpreted as divergence. The Leader Election Problem assumes that all the negotiating processes are terminating. It is however not an easy task to prove that a problem is unsolvable in a particular process model.

Solutions to the Leader Election Problem are often required to satisfy additional properties like distribution, symmetry and stability [Palamidessi 2003]. In fact it has been suggested that adding more structures is one way to achieve sharper separation results [Vigliotti et al. 2007]. Some of the additional structures are actually syntactical requirements. It is unlikely that a result of a syntactical nature has anything to say about expressiveness. Expressiveness ought to be semantic issue. A proof by counter example, say the Leader Election Problem, can be couched in the following formal terms:

- (1) Single out a process P in \mathbb{L} .
- (2) Assume that there were a subbisimilarity \mathfrak{F} from \mathbb{L} to \mathbb{L}' .
- (3) Derive a contradiction from the assumption $\exists Q.P\mathfrak{F}Q$.
- (4) Conclude that $\mathbb{L} \not\sqsubseteq \mathbb{L}'$.

The steps (1-4) are the standard procedure to prove a negative result in Theory of Interaction. When working in this formal setting, the counter examples are often simple and straightforward. For example it is easy to show that the mixed choice $a + \bar{b}$ cannot be interpreted in the π -calculus with only the separated choices [Fu and Lu 2010]. This counter example is much simpler than the Leader Election Problem.

Let's see an example. Is the random number generator definable in \mathbb{M} ? Take a look at the \mathbb{VPC} -process Rng defined as follows:

$$Rng \stackrel{\text{def}}{=} (c)(\bar{c}(\mathbf{0}) \mid !c(x).(\tau.\bar{c}(\text{succ}(x)) + \tau.\bar{b}(x))).$$

It is clear that $Rng \xrightarrow{\tau} \bar{b}(k) = \mathbf{0}$ for every k . The number k is picked up randomly due to the nondeterminism of the composition operator. But notice that Rng is divergent. So at best it is only a pseudo random number generator. Can we improve upon the solution offered by Rng ? The answer is negative.

LEMMA 6.2. *There does not exist a terminating \mathbb{VPC} -process RN such that all its action sequences are of the form $RN \xRightarrow{\bar{b}(k)} = \mathbf{0}$.*

PROOF. According to the termination condition, RN cannot contain two replication sub-processes that can interact. But then RN must be finite branching and consequently König Lemma implies that RN is only capable of generating a finite number of natural numbers. \square

6.2.2 Operational Correspondence. Two folklore criteria for the operational faithfulness of the translation is given in the next two definitions.

Definition 6.3. The translation \mathcal{T} is *operationally complete* if $P \xrightarrow{\tau} P'$ implies that $\exists Q' \in \mathcal{P}_{\mathbb{M}_1}. \mathcal{T}(P) \Longrightarrow Q' =_w^{\mathbb{M}_1} \mathcal{T}(P')$.

Definition 6.4. The translation \mathcal{T} is *operationally sound* if $\mathcal{T}(P) \xrightarrow{\tau} Q'$ implies that $\exists P' \in \mathcal{P}_{\mathbb{M}_0}. P \Longrightarrow P'$ and $Q' =_w^{\mathbb{M}_1} \mathcal{T}(P')$.

To put things in perspective, suppose \mathcal{T} and \mathcal{T}' are operationally sound and complete. Let's see what is necessary to establish the operational completeness and soundness of the composition $\mathcal{T}; \mathcal{T}'$.

—It is easy to see that in order to prove the completeness of $\mathcal{T}; \mathcal{T}'$, we generally need the following soundness property:

—If $P =_w^{\mathbb{M}_1} Q$ then $\mathcal{T}'(P) =_w^{\mathbb{M}_2} \mathcal{T}'(Q)$.

We also need to make use of the fact that $=_w^{\mathbb{M}_2}$ is a weak bisimulation.

—The soundness of $\mathcal{T}; \mathcal{T}'$ is problematic. Suppose $\mathcal{T}'(\mathcal{T}(A)) \xrightarrow{\tau} A_2$ for some $A \in \mathcal{P}_{\mathbb{M}_0}$. By the soundness of \mathcal{T}' , some A_1 exists such that $\mathcal{T}(A) \Longrightarrow A_1$ and $\mathcal{T}'(A_1) =_w^{\mathbb{M}_2} A_2$. Without loss of generality, assume that $\mathcal{T}(A) \Longrightarrow A_1$ consists of two internal steps, say $\mathcal{T}(A) \xrightarrow{\tau} A'_1 \xrightarrow{\tau} A_1$. By the soundness of \mathcal{T} , some A_0 exists such that $A \Longrightarrow A_0$ and $\mathcal{T}(A_0) =_w^{\mathbb{M}_1} A'_1$. To continue, we need to use the property that $=_w^{\mathbb{M}_1}$ is a weak bisimulation. We get some A''_1 such that $\mathcal{T}(A_0) \Longrightarrow A''_1 =_w^{\mathbb{M}_1} A_1$. We are back to square one since $\mathcal{T}(A_0) \Longrightarrow A''_1$ could contain more than one internal step.

So Definition 6.4 is not as innocent as it seems. There are two ways to get over the problem with the soundness. One is to turn the maps $\mathcal{T}, \mathcal{T}'$ into relations, which leads to the idea of weak subbisimilarity, where a weak subbisimilarity generalizes a subbisimilarity in that the former is a weak bisimulation, not necessarily a bisimulation. The other is to strengthen the operational soundness in the manner of the next definition.

Definition 6.5. The translation \mathcal{T} is *truly operational sound* if $\mathcal{T}(P) \Longrightarrow Q'$ implies that $P \Longrightarrow P'$ for some $P' \in \mathcal{P}_{\mathbb{M}_0}$ such that $Q' =_w^{\mathbb{M}_1} \mathcal{T}(P')$.

We can now formulate the notion of operational correspondence.

Definition 6.6. The translation \mathcal{T} is *operationally correspondent* if it is operationally complete and truly operationally sound.

The operational correspondence is a basic requirement for a sensible translation. It must be used in combination with other criteria.

6.2.3 Weak Operational Correspondence. In the literature, see for example [Parrow 2006], a weaker version of the operational soundness appears more popular than the operational soundness we have just discussed.

Definition 6.7. A translation \mathcal{T} is *weakly operationally sound* if $\mathcal{T}(P) \xrightarrow{\tau} Q'$ implies $P \Longrightarrow P'$ for some $P' \in \mathcal{P}_{\mathbb{M}_0}$ and $Q' \Longrightarrow Q'' =_w^{\mathbb{M}_1} \mathcal{T}(P')$ for some $Q'' \in \mathcal{P}_{\mathbb{M}_1}$.

Using similar argument as given in Section 6.2.2, one easily sees that the transitivity of the weak operational correspondence poses even a bigger problem. One solution is to strengthen Definition 6.7 in the style of Definition 6.5.

Definition 6.8. A translation \mathcal{T} is *truly weak operationally sound* if $\mathcal{T}(P) \Longrightarrow Q'$ implies $P \Longrightarrow P'$ for some $P' \in \mathcal{P}_{\mathbb{M}_0}$ and $Q' \Longrightarrow Q'' =_{\mathbb{M}_1}^w \mathcal{T}(P')$ for some $Q'' \in \mathcal{P}_{\mathbb{M}_1}$.

Assuming that the translation \mathcal{T} is operational complete and preserves the weak equality, it is easy to show that truly weak operational soundness is transitive.

Weak operational correspondence is often applied when operational correspondence fails. It happens when an encoding introduces extra names. The role of $Q' \Longrightarrow Q''$ is to do away unwanted extra names by completing unfinished simulations.

6.2.4 Equivalence Criterion. When the models $\mathbb{M}_0, \mathbb{M}_1$ are close enough, it is possible to apply the *equivalence criterion*. A typical scenario of using the equivalence criterion looks like this:

- (1) \mathbb{M}_0 is syntactically a submodel of \mathbb{M}_1 .
- (2) The action set of \mathbb{M}_0 is the same as the action set of \mathbb{M}_1 .
- (3) To show that \mathbb{M}_1 is as expressive as \mathbb{M}_0 , one shows that for each process P of \mathbb{M}_1 there is some process Q of \mathbb{M}_0 such that $Q =_{\mathbb{M}_1}^w P$.

The equivalence criterion is often useful when comparing the expressive powers of different variants of a model [Palamidessi 2003]. It is best seen as an application of Definition 4.4 in a special scenario.

6.2.5 Weak Full Abstraction. A translation fails to satisfy the full abstraction property often satisfies the so-called ‘weak full abstraction’ property [Parrow 2006].

Definition 6.9. The translation \mathcal{T} is *weak fully abstract* if the following property holds: $P =_{\mathbb{M}_0}^w Q$ if and only if $\mathcal{T}(P) \approx_{\mathbb{M}_1} \mathcal{T}(Q)$.

In the above definition, $\approx_{\mathbb{M}_1}$ is the equivalence obtained by restricting the set of the observers to the set consisting of the translations of the contexts definable in \mathbb{M}_0 .

If there is another weak fully abstract translation \mathcal{T}' from some \mathbb{M}_1 to \mathbb{M}_2 , a different equivalence $\approx_{\mathbb{M}_2}$ would be used. Since $\approx_{\mathbb{M}_1}$ is strictly weaker than $=_{\mathbb{M}_1}^w$, there is no way to talk about transitivity for the weak full abstraction.

The weak full abstraction must be rejected as a criterion for expressiveness.

6.2.6 Compositionality. Almost all the translations that have been proposed are structural. If the translation of every operator is structural, then the translation of every process is structural. This motivates the following definition by Gorla [Gorla 2008b; 2008a; 2009b; 2009a].

Definition 6.10. The translation \mathcal{T} is *compositional* if for every n -ary operator op of \mathbb{M}_0 there exists some context $C[-, \dots, -]$ of \mathbb{M}_1 with n -holes such that $\mathcal{T}(op(P_1, \dots, P_n)) =_{\mathbb{M}_1}^w C[\mathcal{T}(P_1), \dots, \mathcal{T}(P_n)]$.

Compositionality is clearly transitive. In reality a compositional translation may be stronger than what Definition 6.10 suggests. Take for example Milner’s encoding of the lazy λ -calculus:

$$\llbracket MN \rrbracket(u) \stackrel{\text{def}}{=} (v)(\llbracket M \rrbracket(v) \mid \bar{v}u.\bar{v}(n) \mid !n(w).\llbracket N \rrbracket(w)).$$

The translation of the application is not exactly compositional according to Definition 6.10 since it is parameterized on the names. This example shows that the translation \mathcal{T} in the above definition should be understood in general as a parameterized encoding.

Compositionality is a good property for an encoding to have. From the point of view of expressiveness, it is yet to be seen a convincing argument why a noncompositional interpretation should be ruled out.

6.2.7 Name Invariance. Most translations have the nice property that they are invariant under the change of names. The criterion defined next is part of the *uniformity condition* of Palamidessi [2003]. It is also heavily used in Gorla's work [Gorla 2008b; 2008a; 2009b; 2009a].

Definition 6.11. The translation \mathcal{T} is *name invariant* if $\mathcal{T}(P\beta) \equiv \mathcal{T}(P)\beta$ for every $P \in \mathcal{P}_{\mathbb{M}_0}$ and every name substitution β .

In the statement of Definition 6.11, the substitution β could be either injective or non-injective. Injective name invariance is not that useful. On the other hand non-injective renaming is a bit too strong. There is nothing wrong for a translation that maps the π -process $[a=b]\bar{d}e$ onto $\mathbf{0}$. But clearly every translation \mathcal{T} should render $\mathcal{T}([a=b]\bar{d}e)\beta$ and $\mathbf{0}\beta$ unequal if β is the non-injective substitution $\{b/a\}$.

6.3 On Completeness

There has been no consensus on what it means for a process calculus to be Turing complete. For the restricted question of Turing completeness of the π -calculus, Milner's answer is the most influential [Milner 1992]. His encoding, a typical application of the apparatus of the π -calculus, is given below:

$$\begin{aligned} \llbracket x \rrbracket_a &\stackrel{\text{def}}{=} \bar{x}a, \\ \llbracket \lambda x.M \rrbracket_a &\stackrel{\text{def}}{=} a(x).a(v).\llbracket \lambda x.M \rrbracket_v, \\ \llbracket MN \rrbracket_a &\stackrel{\text{def}}{=} (c)(\llbracket M \rrbracket_c \mid !\bar{c}(f).\bar{c}a.f(w).\llbracket N \rrbracket_w). \end{aligned}$$

It is proved in [Milner 1992] that this encodings of the closed λ -terms both preserve and reflect the operational semantics of the lazy λ -calculus of Abramsky [1988]. In the followup papers [Sangiorgi 1994; 1995] Sangiorgi proved that Milner's encoding is fully abstract with respect to the open applicative bisimilarity on the λ -terms. In [Milner 1992] Milner has also given an interpretation of the call-by-value λ -calculus [Plotkin 1975] in the π -calculus. Encodings into the variants of the π -calculus have been investigated in [Sangiorgi 1993; Fu 1999; Merro and Sangiorgi 2004]. None of these encodings are good for the full λ -calculus [Barendregt 1984]. Recently Cai and Fu [2011] have constructed a fully abstract encoding of the full λ -calculus in the π -calculus with the match/mismatch operator and the guarded choice operator.

Over the last few years the Turing completeness property has been studied for a number of process calculi [Palamidessi 2003; Busi et al. 2004; Maffei and Phillips 2005; Fu and Lu 2010] using the machine model rather than the λ -calculus. Maffei and Phillips [2005] have summarized several criteria for Turing completeness. Their weakest criterion that has appeared in literature can be stated as follows:

TC-0: Let \mathbf{C} be a computation model. A process calculus \mathcal{M} with a canonical equivalence \simeq on the \mathcal{M} -processes is Turing complete if there is a function $\mathbf{e} : \mathbf{C} \rightarrow \mathcal{P}_{\mathcal{M}}$ such that the following statements are valid for each $c \in \mathbf{C}$:

- (i) If $c \rightarrow c'$ then $\mathbf{e}(c) \Longrightarrow P$ for some process P such that $P \simeq \mathbf{e}(c')$.
- (ii) If $\mathbf{e}(c) \xrightarrow{\tau} P$ then $c \rightarrow^* c'$ for some c' such that $\mathbf{e}(c') \simeq P$.
- (iii) c diverges if and only if $\mathbf{e}(c)$ diverges.

TC-0 is useful for establishing undecidable results. It has been used as a statement that asserts Turing completeness [Busi et al. 2003; Lanese et al. 2008]. In our opinion TC-0 is too weak to be a criterion for anything. It is satisfied by some trivial encodings. Let \mathbf{b} for example be a function defined by the following.

$$\mathbf{b}(c) \stackrel{\text{def}}{=} \begin{cases} \mathbf{0}, & \text{if } c \text{ terminates,} \\ \Omega, & \text{if } c \text{ diverges.} \end{cases}$$

The function \mathbf{b} clearly satisfies TC-0. It basically says that all process calculi are Turing complete according to TC-0. The condition TC-0 is very weak because it only talks about the simulations of computations. The encodings defined in [Busi et al. 2003; Lanese et al. 2008] actually satisfy far more properties, say the effectiveness, than TC-0. What Turing completeness is really about is the simulations of functional behaviours. This can be formally stated as follows.

TC-1: Let \mathbf{R} be the model of recursive functions. A process calculus \mathcal{M} with a canonical equivalence \simeq on the \mathcal{M} -processes is Turing complete if there is a function $\mathbf{e} : \mathbf{R} \rightarrow \mathcal{P}_{\mathcal{M}}$ such that the following statements are valid for all $f(x_1, \dots, x_i) \in \mathbf{R}$ and all natural numbers n_1, \dots, n_i :

- (i) If $f(n_1, \dots, n_i) \rightarrow f'$ then $\mathbf{e}(f(\tilde{x})) | \mathbf{e}(n_1) | \dots | \mathbf{e}(n_i) \Longrightarrow P$ for some process P such that $P \simeq \mathbf{e}(f')$.
- (ii) If $\mathbf{e}(f(\tilde{x})) | \mathbf{e}(n_1) | \dots | \mathbf{e}(n_i) \xrightarrow{\tau} P$ then $f(n_1, \dots, n_i) \rightarrow^* f'$ for some f' such that $\mathbf{e}(f') \simeq P$.
- (iii) $f(n_1, \dots, n_i)$ diverges if and only if $\mathbf{e}(f(\tilde{x})) | \mathbf{e}(n_1) | \dots | \mathbf{e}(n_i)$ diverges.

It is not difficult to see that an encoding satisfying TC-1 must not confuse two distinct natural numbers. The consequence is that the recursive functions cannot be interpreted in a trivial fashion. TC-1 appears to be the strongest criterion one could find in the literature. Other weaker forms are more liberal about (ii) and/or (iii). For example the encoding of a recursive function might get stuck or diverge on some inputs even if the recursive function is defined on these inputs. TC-1 and its weaker forms have been used to establish Turing completeness, or the absence of it, of CCS [Busi et al. 2004; Fu and Lu 2010] and Ambient Calculi [D. Hirschhoff and Sangiorgi 2002; Zimmer 2003; Busi and Zavattaro 2004; Maffei and Phillips 2005].

From the point of view of interaction, even TC-1 is subject to criticism. Suppose $f(n_1, \dots, n_i) \rightarrow^* \underline{n}$ and

$$\mathbf{e}(f(\tilde{x})) | \mathbf{e}(n_1) | \dots | \mathbf{e}(n_i) \xrightarrow{\tau} P_1 \xrightarrow{\tau} P_2 \xrightarrow{\tau} \dots \xrightarrow{\tau} P_k \simeq \mathbf{e}(\underline{n}). \quad (21)$$

According to definition $f(n_1, \dots, n_i)$ is computationally equal to \underline{n} . This equality is generally not respected by the encoding \mathbf{e} since it is possible that $P_k \not\simeq P_i$ for

all $i < k$. The consequence is that the simulation of the encoding of a recursive function can be easily interrupted by the environment and an environment is never sure of what it is getting.

There are other variant definitions of the Turing completeness. It suffices to say that none of them meet our requirement on completeness. The encodings of the lazy λ -calculus in the π -calculus for example lack of the mechanism of result delivery. Other encodings appear weaker in that they have neither the input nor the output mechanisms. Although computations can be carried out by these encodings, the results of the computations are not usable to any processes. It is in the light of these facts that the completeness of this paper should be appreciated.

The notion of completeness is so important to Theory of Interaction that a correct formulation of the notion is of paramount importance.

7. CONCLUSION

The most significant contribution of this paper is the model independent formulation of the two most important relationships in Computer Science, the expressiveness relationship between the models and the equality relationship between the objects of a model. The mere fact that the Axiom of Completeness can be formally stated is itself a manifestation. The uniform definition of the equality and the expressiveness is a technical advance, making it clear how the expressiveness relationship can be unique and why the full abstraction is a natural requirement.

Theory of Interaction provides a number of guidelines when introducing a new model \mathbb{N} . The following two questions must be addressed:

- Is \mathbb{N} complete?
- Is the absolute equality a congruence?

Technically the most important question is the following

- What is its external characterization of the absolute equality on \mathbb{N} ?

More information about \mathbb{N} can be obtained by answering harder questions. Theory of Interaction allows one to formalize these questions without any ambiguity.

What is carried out in this paper is the starting point for many things to follow. In sequel we point out some open problems and research directions.

7.1 Open Problem

The \mathbb{C} -calculus plays a fundamental role in Theory of Interaction. The absence of the localization operator is attractive due to its simplicity. But it also raises questions. What would be the observational theory if the localization operator is incorporated into \mathbb{C} ? Let \mathbb{I} be \mathbb{C} extended with the localization operator. From the point of view of completeness the most significant question is this: Can completeness be defined in terms of \mathbb{I} ? In other words, is \mathbb{I} the least expressive model of interaction? The solution to the problem may heavily depend on the observational theory of \mathbb{I} .

Problem 7.1. What is the observational theory of \mathbb{I} ?

At the moment we do not even know if $\mathbb{I} \sqsubseteq \pi$ holds.

Fig. 2. An Infinite C -Graph

The C -graphs introduced in 3.2 are interesting on their own. A lot has to be learned before we can make any useful statements about them. Future studies could address three issues. Firstly we may investigate the possibility of deducing the elements of \mathcal{U}_{i+1} from those of \mathcal{U}_i . As a warming-up exercise we may find it beneficial to work out the elements of $\mathcal{U}_4, \mathcal{U}_5, \mathcal{U}_6$ and etc.. A related issue is to produce a formula with which we can calculate the size of \mathcal{U}_i . Secondly we can try to answer the question: are the set of the unobservable π -process the same as the set of the unobservable \mathbb{VPC} -processes? We may even address the following more general question: are the unobservable objects model independent? Thirdly we need to study the definability of the infinite C -graphs in a particular model. Infinite C -graphs do exist. Fig. 2 provides an example, where ‘ \circ ’ represents a node with a self-loop. It is not yet clear if this infinite C -graph represents an unobservable process in say the π -calculus. A solution to this problem will be both conceptually and technically instructive.

Problem 7.2. What is the theory of C -graph?

For the models without the choice operator, the problem one comes across when attempting to prove the coincidence is to do with the bisimulations of the input actions. Take the π -calculus for instance. Suppose $P =_{\pi} Q \xrightarrow{ac} Q'$ and d is a fresh name. Now $Q | \bar{a}c.d | \bar{d} \xrightarrow{\tau} \tau \rightarrow Q'$ must be simulated by some $P | \bar{a}c.d | \bar{d} \xrightarrow{\tau} P'$. From the latter internal action sequence it is easy to derive $P \xrightarrow{ac} P'$. But so far we have not been able to show that the simulation must take the form $P \rightarrow^* \xrightarrow{ac} P'$. This issue is technically important and practically useful. It is worth stating as an open problem.

Problem 7.3. What is the observational theory of π^M ?

If the external bisimilarity turns out to be the same as given in Definition 3.19, we may immediately conclude that $\pi^M \sqsubseteq \pi$.

Section 4.4 tells us that there are possibly many incompatible interpretations of a complete model into itself. It also suggests that incompatible interpretations are often caused by different encoding-decoding functions. The picture of the self interpretations on \mathbb{VPC} will not be fully understood until we answer the following.

Problem 7.4. Is every self interpretation on \mathbb{VPC} induced by a bijective computable function?

Fig. 3. The World of Models

7.2 Future Direction

Future studies in Theory of Interaction may stretch in several directions.

- (1) The first direction is to expand the current picture, given by the diagram in Fig. 3, of the world of the interaction models. The model π^L , called local π by Merro and Sangiorgi [2004], is the π -variant in which a name received from a communication cannot be used as an input channel. Symmetrically π^R [Fu and Zhu 2011] is the π -variant in which a name received from a communication cannot be used as an output channel. Another π -variant, called π^S in [Fu and Zhu 2011], is defined by imposing the restriction that the received names can only be used as channel names (subject names). The expressiveness of π^L, π^S, π^R is studied in [Xue et al. 2011]. A sensible thing to do is to examine the other major process models not yet discussed in this paper. One could compare along the way the existing expressiveness results against the results obtained by applying the subbisimilarity relationship. There is little doubt that exercises of this sort would bring to us new insight into the process models.
- (2) The second direction is to apply the model independent philosophy of Theory of Interaction to other frameworks. If we go about the plan in the order of the equality theory, the expressiveness theory and the completeness theory, we should start from the picture described in Fig. 4. All equalities for models of interaction should be observational. In other words they must satisfy the extensionality and equipollence conditions. So every equality is above the extensional equality introduced by Definition 6.1. On the other hand, the bisimulation and codivergence conditions are the strongest intensional (computational) requirements one may impose on the observational equalities. Consequently every equality is under the absolute equality. Now suppose $=_t$ is a model independent equality that lies between the extensional equality and the absolute equality. The definition of $=_t$ either strengthens the extensional condition, or weakens the intensional condition, or is a mixture of both. Due to its model independent nature, the definition can be routinely generalized to the expressiveness relationship. The rest of the job is to develop the expressiveness theory and the completeness theory that go along with $=_t$. The views and the results obtained along this line of research would certainly improve our understanding of the interaction models. The model independent approach can also be applied to the study of the pre-orders on processes. A recent progress along this line of

Fig. 4. The World of Equalities

investigation is reported in [He 2010].

- (3) The third direction is to rework the concurrency theory in the light of Theory of Interaction. There are many aspects one could inspect. One may try to formulate the asynchronous theory [Honda and Tokoro 1991a; 1991b; Boudol 1992; Amadio et al. 1998] in Theory of Interaction. Initial progress on this topic is reported in [Fu 2010]. One may apply the principles of Theory of Interaction to the Petri Net Model [Reisig 1985] so that the problem of compositionality is solved in a satisfactory way. Theory of Interaction provides a method, as well as a toolkit, to shrink the bulk of the concurrency theory by streamlining the models.
- (4) The fourth direction is to integrate the theory of computation [Dasgupta et al. 2006; Papadimitriou 1994; Wegener 2005] into Theory of Interaction. Since every interaction model is complete, one may carry out algorithm design and complexity analysis in an interaction model. The additional help Theory of Interaction might provide is a formal treatment of the distinctions between the determinism and the nondeterminism. The hope is that by expanding the computation theory into the dimension of interaction, nondeterminism can be dealt with at the model level rather than at the algorithmic level.
- (5) The fifth direction is to explore the tools developed in Theory of Interaction to search for significant negative results. The theory of process calculus is a theory abundant in models. It is also a theory that is by and large flat. The lack of deep negative results supports the flat theory view. Finkel and Schnoebelen explain in [Finkel and Schnoebelen 2001] how the well quasi order structure [Kruskal 1972] can be used to derive a number of results in concurrency theory. The same structures are used in obtaining some negative results in process theory [Busi et al. 2003; 2004; Fu and Lu 2010]. Another interesting negative result is Sewell's theorem on the nonexistence of a finite axiomatic system of the finite state processes [Sewell 1994; 1995; 1997]. There are not many such examples. The meta theoretical framework offered by Theory of Interaction ought to be helpful in obtaining general negative results.

So Theory of Interaction not only offers a framework, it also offers problems.

There are a lot to do.

ACKNOWLEDGMENTS

This work has been supported by NSFC (60873034, 61033002). The author would like to thank the members of BASICS for their interest, discussions and feedbacks. The author has benefited a lot from the discussions with professor Mingsheng Ying on the topics of this paper. He is grateful to Huan Long and Jianxin Xue who have discovered a number of serious mistakes in the drafts of the paper. In particular they demonstrated to me that my original perception about the self interpretations on the π -calculus was terribly wrong. Huan Long pointed it out to me that the tricks used in the proof of Theorem 4.23 can be reused to tell apart the polyadic π from the monadic π . Li Han, Chunzhi Su and Linpeng Tang have convinced me that my original example used in the proof of Lemma 3.22 was wrong.
